Mechanically verifying the correctness of an offline partial evaluator

John Hatcliff ‡

Abstract

We show that using deductive systems to specify an offline partial evaluator allows its correctness to be mechanically verified.

For a λ-mix-style partial evaluator, we specify binding-time constraints using a natural-deduction logic, and the associated program specialist using natural (aka “deductive”) semantics. These deductive systems can be directly encoded in the Elf programming language — a logic programming language based on the LF logical framework. The specifications are then executable as logic programs. This provides a prototype implementation of the partial evaluator.

Moreover, since deductive system proofs are accessible as objects in Elf, many aspects of the partial evaluation correctness proofs (e.g., the correctness of binding-time analysis) can be coded in Elf and mechanically verified.

This work illustrates the utility of declarative programming and of using deductive systems for defining program specialization systems: by exploiting the logical character of definitions, one may specify, prototype, and mechanically verify correctness via meta-programming — all within a single framework.

1 Introduction

As the application of program-specialization techniques increases, it is important to study ways of formally specifying and proving these techniques correct. Unfortunately, relatively few specialization systems have been proven correct, and we are not aware of any that have been mechanically verified. Even when systems have been proven correct, it is unclear from the literature which styles of formalization are preferable.

As an example, consider offline partial evaluation of functional programs [5, 20]. This consists of two phases: a binding-time analysis phase (where information is gathered about what parts of the source program depend on known or unknown data), and a specialization phase (where constructs depending on known data are reduced away). Denotational semantics has been the most widely applied formalism for specifying offline partial evaluators. The denotational method allows both phases to be specified in the same framework: the analysis phase is specified as an abstract interpretation [6, 21] and the specialization phase is specified as a function from a source program to a residual program. Moreover, a prototype implementation can often be obtained by a fairly straightforward (though informal) transliteration of the denotational specifications into functional programs.

Recent work specifies the analysis phase using type systems while the specialization phase is specified denotationally [10, 22]. Unfortunately, this approach loses a degree of synergy since both phases are not specified in the same framework. For example, one can no longer obtain a prototype via a simple translation to functional programs (since the typing rules which specify the analysis cannot be simply translated). Others define the

program specializer using operational semantics and thus avoid what Wand has characterized as a "morass of model-theoretic details" [37] associated with the denotational framework.

Note that the type system and operational semantics formalisms can be unified if one emphasizes their logical character: a type-based analysis is a logic for deducing program properties, and an operational semantics is a logic for deducing computational steps or input/output behaviour of programs. However, in program specialization systems that use these formalisms, this logical character has neither been emphasized nor exploited.

In this paper, we exploit the logical character of such deductive systems and obtain a uniform framework for specifying, prototyping, and mechanically verifying the correctness of program specialization systems. Specifically, we consider offline partial evaluation in the style of the partial evaluator $\lambda$-mix [11]. $\lambda$-mix is a good illustrative case since it is simple, and one of the few partial evaluators with a rigorous semantic foundation. It has also spawned additional work on the correctness of binding-time analysis and specialization [27, 37].

The results of the present work are as follows.

- We give specifications of binding-time constraints and specialization as natural-deduction style logics. These specifications simplify meta-theory activities such as proving the correctness of binding-time analysis and specialization.

- We formalize the specifications using LF — a meta-language (a dependently-typed $\lambda$-calculus) for defining logics [19]. In LF, judgements (assertions) are represented as types, and deductions are represented as objects. Determining the validity of a deduction is reduced to checking if the representing object is well-typed. Since LF type-checking is decidable, purported deductions can be checked automatically for validity.

- We obtain prototypes directly from the formal specifications using Elf — a logic programming language based on LF [29]. Elf gives an operational interpretation to LF types by treating them as goals. Thus, the LF specifications of the binding-time analysis and specializer are directly executable in Elf.

- We formalize and mechanically verify much of the meta-theory of offline partial evaluation (e.g., correctness of binding-time analysis and soundness of the specializer) via meta-programming in Elf. Correctness conditions are formalized as judgements about "lower-level" deductions describing object-language evaluation and transformation. Proofs of correctness are formalized as deductions of the correctness judgements. Elf type-checking mechanically verifies that these deductions (and hence the correctness proofs) are valid.\(^2\)

This methodology of specification/implementation/verification using LF and Elf has been successfully applied in other problem areas [18, 23]. In particular, we build on Hannan and Pfenning's work on compiler verification in Elf [18]. They conjectured that their techniques could also be applied to partial evaluation [18, p. 416]. They also identify the verification of transformations based on flow analyses as a "challenging problem, yet to be addressed" [18, p. 415]. The present work addresses both of these points. We confirm their conjecture that LF and Elf can be used for specification/implementation/verification of partial evaluators. Moreover, we give one instance where transformations based on flow analyses can be verified — namely, the specialization of programs based on binding-time analysis. Hannan has recently reported on a second instance: the use of Elf to encode a type system for closure conversion [16].

The rest of the paper is organized as follows. Section 2 summarizes LF and Elf. Section 3 presents the object language and its encoding in Elf. Section 4 presents the specifications of the binding-time analysis and specializer. Section 5 illustrates how these specifications are executable in Elf. Section 6 shows how meta-theoretic properties of the specifications can be mechanically verified. Section 7 surveys related work, and Section 8 concludes.

2 LF and the Elf Programming Language

This section presents a very brief overview of LF and Elf. The reader is referred to the original work on LF by Harper, Honsell, Plotkin [19] for a detailed presentation of LF. Pfenning [29] gives the technical foundations of

---

\(^1\)Our setting differs from that of $\lambda$-mix in two ways: (1) we are not concerned with self-applying the partial evaluator, and (2) our object language is typed while $\lambda$-mix's is untyped. However, the techniques here apply equally well to the untyped object language of $\lambda$-mix (in fact, they are simpler in the untyped case).

\(^2\)This paper contains all the required Elf code and is implemented using version 0.3 of Elf. The code is available upon request from the author.
Elf. Papers by Hannan and Pfenning [18] and Michaylov and Pfenning [23] give applications of Elf that provide the main techniques used in the present work.

2.1 LF — a framework for defining logics

The LF calculus has three levels: objects, families, and kinds. Families are classified by kinds, and objects are classified by types, i.e., families of kind type.

\[ K ::∵ Type \mid \Pi x : A, K \]

\[ A ::∵ a \mid \Pi x : A_1, A_2 \mid \lambda x : A_1. A_2 \mid A M \]

Family-level constants are denoted by \( a \), and object-level constants by \( c \). \( A_1 \to A_2 \) abbreviates \( \Pi x : A_1, A_2 \) and \( \Pi x : A. K \) when \( x \) does not appear free in \( A_2 \) or \( K \), respectively. The typing rules for LF can be found in [19]. We take \( \beta \eta \)-equivalence as the notion of definitional equality in LF [19, Appendix A.3]. For all the languages we consider, we identify terms up to renaming of bound variables.

One defines a logic in LF by specifying a signature which declares the kinds of family-level constants \( a \) and types of object-level constants \( c \). These constants are constructors for the logic’s syntax, judgements, and deductions. Well-formedness is enforced by LF type-checking. The LF type system can represent the conditions associated with binding operators, with schematic abstraction and instantiation, and with the variable occurrence and discharge conditions associated with rules in systems of natural deduction.

2.2 Elf — an implementation of LF

The syntax of Elf is as follows (the last column lists the corresponding LF term). Optional components are enclosed in \( \langle \rangle \).

\[ kindexp ::= type \mid \langle \text{type} \rangle \]

\[ family ::= id \mid \langle \text{id} \rangle \]

\[ object ::= id \mid \langle \text{id} \rangle \]

The terminal \( id \) ranges over variables, and family and object constants. Bound variables and constants in Elf can be arbitrary identifiers, but free variables in a declaration or query must begin with an upper case letter. Free variables act as logic variables and are implicitly \( \Pi \)-abstracted. Elf’s term reconstruction phase (preprocessing) inserts these abstractions as well as appropriate arguments to these abstractions. It also fills in the omitted types in quantifications \( \{ x \} \) and abstractions \( \{ x \} \) and omitted types or objects indicated by an underscore \( _\_ \).

The \( \leftarrow \) is used to improve the readability of some Elf programs. \( B \leftarrow A \) is parsed into the same representation as \( A \rightarrow B \); \( \rightarrow \) is right associative, while \( \leftarrow \) is left associative. An Elf program is a representation of an LF signature. Although we are implicitly encoding logics in LF, we give all encodings using the syntax of Elf.

3 The Object Language

3.1 Syntax
Object language:

\[
e \in \text{Exp} \\
e ::= x \mid 0 \mid \text{sc} e \mid \text{pr} e \mid \text{if} 0 e_1 e_2 e_3 \\
\text{lam} x . e \mid \text{app} e_0 e_1 \mid \text{fix} x . e
\]

Elf encoding:

\[
\text{exp} : \text{type}. \\
\text{typ} : \text{type}. \\
z : \text{exp}. \\
\text{sc} : \text{exp} \to \text{exp}. \\
\text{pr} : \text{exp} \to \text{exp}. \\
\text{if} : \text{exp} \to \text{exp} \to \text{exp} \to \text{exp}. \\
\text{lam} : (\text{exp} \to \text{exp}) \to \text{exp}. \\
\text{app} : \text{exp} \to \text{exp} \to \text{exp}. \\
\text{fix} : (\text{exp} \to \text{exp}) \to \text{exp}.
\]

Figure 1: The object language $\Lambda$

Figure 1 presents the syntax of the object language $\Lambda$ (a PCF-like language) and its encoding in Elf. We identify object-level terms up to $\alpha$-equivalence (i.e., up to renaming of bound variables). We write $e_1 \equiv e_2$ when $e_1$ and $e_2$ are $\alpha$-equivalent.

The Elf signature for the object language syntax includes family constants $\text{exp}$ and $\text{typ}$, and object constants for each term and type constructor. Variable binding in $\text{lam} x . e$ and $\text{fix} x . e$ is represented using binding in the meta-language (i.e., using higher-order abstract syntax [31]) — an idea going back to Church [3]. For example, the expression

\[
\text{app} (\text{lam} x_1 \cdot \text{lam} x_2 \cdot \text{app} (\text{lam} x_3 . x_3) x_1) 0
\]

is encoded as

\[
\text{app} (\text{lam} [x_1] \cdot \text{lam} [x_2] \cdot \text{app} (\text{lam} [x_3] . x_3) x_1) z.
\]

In this style of encoding, the body of the $\text{lam}$ expression

\[
\text{lam} x_1 . \text{lam} x_2 . \text{app} (\text{lam} x_3 . x_3) x_1
\]

is represented as a “higher-order term” that maps expressions to expressions. This allows substitution in the object language to be represented using Elf application and $\beta$-reduction. For example,

\[
(\text{lam} x_2 . \text{app} (\text{lam} x_3 . x_3) x_1) [x_1 := z]
\]

is represented in Elf as

\[
([x_1] \cdot \text{lam} [x_2] \cdot \text{app} (\text{lam} [x_3] . x_3) x_1) z.
\]

An Elf $\beta$-reduction gives the expected result of the substitution.

\[
\text{lam} [x_2] \cdot \text{app} (\text{lam} [x_3] . x_3) z
\]

This representation properly implements capture-free object-level substitution since it is expressed via Elf substitution (which the Elf implementation guarantees to be capture-free). Note that since variables in the object language are identified with variables in the meta-language, there is no explicit representation of identifiers in the Elf signature for the object language.

Technically, one must ensure that encodings of syntax into Elf are adequate, i.e., that there is a compositional bijection between the syntactic entities in the logical system and well-formed LF long $\beta\eta$-normal forms under the given signature. An adequate encoding ensures that each entity is encoded uniquely and that no representations of additional entities are introduced. All the encodings we use are adequate. See Harper et al. [19] for a detailed discussion and proofs of adequacy for encodings similar to the ones used here.

\end{align*}\]

Figure 2: The typing rules for \( \Lambda \)

3.2 Typing

3.2.1 Natural deduction style rules

Figure 3 presents the typing rules for \( \Lambda \) in a natural-deduction style logic (we use the notation of Prawitz [33]). Parentheses in the hypotheses of the rules \( \text{tp}_\text{lam} \) and \( \text{tp}_\text{fix} \) indicate the discharging of zero or more occurrences of assumptions. We write \( T \vdash \text{tp} \ e : \tau \) when \( \text{tp} \ e : \tau \) is derivable under undischarged assumptions \( T \). We shall only be concerned with assumptions involving identifiers (e.g., \( \text{tp} \ x : \tau \)) since the logic only allows discharging of assumptions of this form. For simplicity, we require identifiers \( x_i \) in assumption sets \( T = \{ \text{tp} \ x_1 : \tau_1, \ldots, \text{tp} \ x_n : \tau_n \} \), to be pairwise distinct.

3.2.2 Elf encoding

Figure 3 presents the Elf encoding of the typing rules. The figure begins with a declaration of the typing judgement \( \text{tp} \) as a relation between source expressions \( \text{exp} \) and types \( \text{typ} \). The implicit universal quantification of the upper case variables captures the schematic nature of the rules. The rules for binding constructs \( \text{lam} \) and \( \text{fix} \) (which involve hypothetical proofs in the premises) are encoded in Elf as proof constructors that take proofs of hypothetical judgements as arguments. Such proofs are represented as functions mapping proofs of assumption judgements to proofs of consequent judgements. The higher-order syntax representation requires that judgements involving identifiers be represented as schematic judgements (i.e., identifiers are \( \Pi \)-quantified). This is the case in rules \( \text{tp}_\text{lam} \) and \( \text{tp}_\text{fix} \) where e.g., the judgement \( \text{tp} \ (\text{E} \ x) \ T2 \) expresses that \( \text{E} \) may be instantiated to representations of terms with free occurrences of \( x \) [19, Section 3.1].

\end{align*}\]

Figure 4: The natural semantics rules for \(\Lambda\) (interpretation logic)

### 3.2.3 Executing the specification

The Elf encoding of the typing rules (see Figure 3) is an executable logic program. For example, type inference for the example expression of Section 3.1 can be performed via the following Elf query.

?- \text{tp} \ (\text{app} \ (\text{lam} \ [x1] \ \text{lam} \ [x2] \ \text{app} \ (\text{lam} \ [x3] \ x3) \ x1) \ z) \ T.

Solving...

\[T = \text{arrow} \ T1 \ \text{nat}.
\]

no more solutions

The solution \(T = \text{arrow} \ T1 \ \text{nat}\) indicates that the example expression is a function yielding results of type \text{nat} for any argument type \(T1\).

### 3.3 Operational Semantics

#### 3.3.1 Natural deduction style rules

Figure 4 presents the call-by-name natural semantics rules (i.e., the \textit{interpretation} or \textit{evaluation} logic) for \(\Lambda\) terms. These rules correspond to the usual call-by-name “natural” or “deductive” operational semantics for PCF [14, Chapter 4]. We write \(\vdash c \overset{\psi_{\text{int}}}{\rightarrow} a\) when \(c \overset{\psi_{\text{int}}}{\rightarrow} a\) is derivable, and \(c \overset{\psi_{\text{int}}}{\rightarrow}\) when there does not exist an \(a\) such that \(\vdash c \overset{\psi_{\text{int}}}{\rightarrow} a\). It is easy to check that the relation induced by \(\psi_{\text{int}}\) is a partial function.

Two terms are considered \textit{operationally equivalent} if they cannot be distinguished by any program context [14, Chapter 6].
\begin{verbatim}
%% interpreter judgement
int : exp -> exp -> type.

%% interpreter axioms and rules
int_z : int z z.
int_sc : int (sc E) (sc A) <- int E A.
int_prz : int (pr E) z <- int E z.
int_prsc : int (pr E) A <- int E (sc A).
int_ifz : int (if E1 E2 E3) A <- int E1 z <- int E2 A.
int_ifsc : int (if E1 E2 E3) A <- int E1 (sc A1) <- int E3 A.
int_lam : int (lam E) (lam E).
int_app : int (app E0 E1) A <- int E0 (lam E0') <- int (E0' E1) A.
int_fix : int (fix E) A <- int (E (fix E)) A.
\end{verbatim}

Figure 5: The Elf encoding of the natural semantics rules (interpreter)

Definition 1 (Operational Equivalence) \( e_1, e_2 \in \Lambda \) are operationally equivalent (written \( e_1 \approx e_2 \) if for all contexts \( C \) such that \( \vdash tp e_1 : \text{nat} \) and \( \vdash tp e_2 : \text{nat} \) one of the following holds:

1. \( e_1 \triangleright_{int} \) and \( e_2 \triangleright_{int} \), or
2. \( \vdash e_1 \triangleright_{int} a_1 \) and \( \vdash e_2 \triangleright_{int} a_2 \) and \( a_1 \equiv a_2 \).

Section 6 shows that our partial evaluator produces an output program that is operationally equivalent to the given input program.

3.3.2 Elf encoding

Figure 5 gives the Elf encoding of the natural semantics. The encoding techniques are similar to those used by Michaylov and Pfennig [23]. In the rules \texttt{int_app} and \texttt{int_fix}, we take advantage of the higher-order abstract syntax representation and use Elf application (\textit{i.e.}, \( \beta \)-reduction) to implement capture-free substitution.
3.3.3 Executing the specification

As with the typing rules, the Elf encoding of the natural semantics rules (see Figure 5) is an executable logic program. For example, evaluation of the example expression of Section 3.1 can be performed via the following Elf query.

?- int (app (lam [x1] lam [x2] app (lam [x3] x3) x1) z) A.

A = lam [x2:exp] app (lam [x3:exp] x3) z.

; no more solutions

3.3.4 Canonical terms of evaluation

An examination of the rules of Figure 4 reveals that the canonical terms (i.e., values) of evaluation are either 0, \( \text{sc} \ e \) where \( e \) is also canonical, and \( \text{lam} \ x, e' \). We formalize the notion of canonical term with the judgement \( \text{val} \) of Figure 6. The encoding of the value rules in Elf is straightforward.

The following proposition formalizes the above claim: terms satisfying the value judgement \( \text{val} \) are indeed the results of evaluation.

**Proposition 1** If \( \vdash e \ \psi_{int} \ e' \), then \( \vdash \text{val} \ e' \)

The proof of this proposition proceeds by induction over derivations of \( e \ \psi_{int} \ e' \); it can be formalized and mechanically checked in Elf. The reader is referred to the work of Michaylov and Pfenning [23] where a detailed presentation of such a proof for call-by-value evaluation is given.

Finally, note that we have followed convention [14] and defined the value judgement on the syntactic category of expressions while omitting any notion of typing. Thus, the judgement does not enforce well-typedness and admits terms that would not result from the evaluation of a well-typed program. For example, \( \vdash \text{val} \ \text{sc} \ (\text{lam} \ x, x) \) but there does not exist a \( \tau \) such that \( \vdash \text{typ} \ \text{sc} \ (\text{lam} \ x, x) : \tau \). Well-typedness of values is expressed by using the typing judgement in conjunction with the value judgement.

4 Specifying an Offline Partial Evaluator for \( \lambda \)

A partial evaluator takes a source program \( p \) and a subset \( s \) of \( p \)'s input, and produces a residual program \( p_s \), which is specialized with respect to \( s \). The correctness of the partial evaluator implies that running \( p_s \) on \( p \)'s remaining input \( d \) gives the same result as running \( p \) on the complete input \( s \) and \( d \). The data \( s \) and \( d \) are
Annotated object language:

\[
\begin{align*}
    w & \in S\text{exp} & m & \in S\text{der} \\
    w & ::= y \mid 0_m \mid s\text{c}_m w \mid pr_m w \mid if_0_m w_1 w_2 w_3 \mid \\
    & | \text{lam}_m y. w \mid \text{app}_m w_0 w_1 \mid \text{fix}_m y. w \mid \\
    & | \text{lift} w
\end{align*}
\]

    \text{bz} & : \text{sder} \to \text{sexp}. & s & : \text{sder}. \\
    \text{bse} & : \text{sder} \to \text{sexp} \to \text{sexp}. & d & : \text{sder}. \\
    \text{bpr} & : \text{sder} \to \text{sexp} \to \text{sexp}. \\
    \text{bif} & : \text{sder} \to \text{sexp} \to \text{sexp} \to \text{sexp} \to \text{sexp}. \\
    \text{blam} & : \text{sder} \to (\text{sexp} \to \text{sexp}) \to \text{sexp}. \\
    \text{bapp} & : \text{sder} \to \text{sexp} \to \text{sexp} \to \text{sexp}. \\
    \text{bfix} & : \text{sder} \to (\text{sexp} \to \text{sexp}) \to \text{sexp}. \\
    \text{lift} & : \text{sexp} \to \text{sexp}. \\
\end{align*}
\]

Figure 7: The annotated object language $A_{abt}$

often referred to as static and dynamic data (respectively) since $s$ is fixed at specialization time whereas one may supply various data $d$ during runs of $p_s$.

The specialized program $p_s$ is obtained from $p$ by evaluating constructs that depend only on $s$, while rebuilding constructs that may depend on dynamic data. Offline partial evaluation accomplishes this in two phases: (1) a binding-time analysis phase; and (2) a specialization phase.

1. **Binding-time analysis**: Given assumptions about which program inputs are static and dynamic, binding-time analysis constructs an annotated program where each program construct is annotated with a specialization directive and a specialization type.

   - **Specialization directives**: A construct is assigned a directive of eliminable if it depends only on static data and thus can be completely evaluated during the specialization phase. A construct is assigned a directive of residual if it may depend on dynamic data and thus must be reconstructed in the specialization phase.

   - **Specialization types**: The specialization types (a.k.a binding times) are the carriers of information during the analysis phase. They describe the “knownness” or the “unknownness” of expressions. This information is used to determine the specialization directives assigned to constructs. For example, if the argument of a destructor construct has a specialization type indicating that it is unknown, then that construct cannot be evaluated at specialization time and must be given a residual directive.

2. **Specialization**: During the specialization phase, the specializer simply follows the directives assigned during binding-time analysis: eliminable constructs are evaluated (and thus eliminated); residual constructs are reconstructed (and thus appear in the residual program).

Several different formalizations of binding-time analysis and specialization are given in the literature (see the textbook of Jones et al. [20] for a survey). In the remainder of this section, we give a logical formalization that is suitable for encoding in Elf.

4.1 *Binding-time analysis*

We first outline how binding-time information is expressed in a program annotated with specialization directives and types. Following this, we give a binding-time logic that determines which annotations are appropriate for a given source language term.
4.1.1 Specialization directives

A binding-time analysis for $\Lambda$ associates each $\Lambda$ term with a term in the annotated language $\Lambda_{\text{bs}}$ of Figure 7. An annotated term is indexed by a specialization directive $s$ or $d$ indicating if it is eliminable (i.e., it depends only on static data and thus can be eliminated at specialization time) or residual (i.e., it may depend on dynamic data and thus must be placed in the residual program). Identifiers are not indexed since the appropriate information can be determined from the environment. A coercion construct lift is added to $\Lambda_{\text{bs}}$ to residualize the result of evaluating an eliminable term. This allows static computation to occur in a residual context (an example is given in Section 4.3). A term $w \in \Lambda_{\text{bs}}$ is completely residual if it consists of only $d$-indexed constructs and identifiers. For example, the following well-annotated version of the example expression of Section 3.1 is completely residual.

$$\text{app}_{d} (\text{lam}_{d} y_{1}, \text{lam}_{d} y_{2}, \text{app}_{d} (\text{lam}_{d} y_{3}, y_{3}) y_{1}) 0_{d}$$

Intuitively, the specializer will output completely residual terms — all eliminable constructs will have been evaluated (this will be proven in Section 6.1). The Elf encoding of $\Lambda_{\text{bs}}$ terms follows that of $\Lambda$ terms (except that directive indexing is captured by supplying an extra argument of type \text{scheduler} to a constructor). For example, the term above is encoded as follows.

$$\text{bapp} d (\text{blam} d [y_{1}] (\text{blam} d [y_{2}] (\text{bapp} d (\text{blam} d [y_{3}] y_{3}) y_{1})) (b z d)$$

4.1.2 Specialization types

Figure 8 presents a $\tau$-indexed family of specialization types for $\Lambda_{\text{bs}}$ (we omit type indices on specialization types when they can be inferred from the context). A specialization type $\varphi$ is dynamic if $\varphi = \text{dyn}$; otherwise $\varphi$ is static. The intention is that

- $\text{sta} \in \text{Styp}[\text{nat}]$ will tag expressions of type $\text{nat}$ that are guaranteed to evaluate to known data (i.e., numerals $0$, $\text{sc} 0$, etc.);
- $\text{dyn}_{\text{nat}} \in \text{Styp}[\text{nat}]$ will tag expressions of type $\text{nat}$ whose evaluation may depend on unknown data and thus cannot be guaranteed to evaluate to numerals;
- $\varphi_{\tau_{1}} \rightarrow \varphi_{\tau_{2}} \in \text{Styp}[\tau_{1} \rightarrow \tau_{2}]$ will tag expressions of type $\tau_{1} \rightarrow \tau_{2}$ that are guaranteed to evaluate to known data (i.e., abstractions);
- $\text{dyn}_{\tau_{1} \rightarrow \tau_{2}} \in \text{Styp}[\tau_{1} \rightarrow \tau_{2}]$ will tag expressions of type $\tau_{1} \rightarrow \tau_{2}$ whose evaluation may depend on unknown data and thus cannot be guaranteed to evaluate to an abstraction.

Specialization types are encoded in Elf via the type family $\text{styp}: \text{typ} \rightarrow \text{type}$. For the $\text{dyn}$ and $\text{barrow}$ constructors, the type indices are encoded as logic variables $T$, $T_{1}$, and $T_{2}$, which will be instantiated by unification. This formalizes the above convention of allowing type indices to be inferred from the context.

4.1.3 Binding-time logic

Figure 9 presents a natural-deduction-style logic for deriving judgements of the form $\text{bta} e : \tau [w : \varphi_{\tau}]$. Parentheses in the hypotheses of the rules for binding constructs (i.e., $\text{bta} \text{lam}_{s}, \text{bta} \text{lam}_{d}, \text{bta} \text{fix}_{s}, \text{bta} \text{fix}_{d}$) indicate
the discharging of zero or more occurrences of assumptions. We write \( \Gamma \vdash \text{bta} \ e : \tau [w : \varphi_\tau] \) when \( \text{bta} \ e : \tau [w : \varphi_\tau] \)

is derivable under undischarged assumptions \( \Gamma \).

Derivable judgements specify constraints that an actual binding-time analysis algorithm must satisfy. Intuitively, if \( \Gamma \vdash \text{bta} \ e : \tau [w : \varphi_\tau] \), then given initial binding-time assumptions \( \Gamma \), a binding-time analysis algorithm may map \( e \in \text{Terms}[\Lambda] \) of type \( \tau \in \text{Type}s[\Lambda] \) to a directive annotated term \( w \in \text{Terms}[\Lambda_\kappa] \) of specialization type \( \varphi_\tau \in \text{Spec-types}[\tau] \). Specifying the analysis in this way allows one to reason about correctness of the analysis independently of the actual algorithm — proving correctness with respect to the constraints implies that any algorithm satisfying the constraints will be correct. Furthermore, Section 5.1 shows how the Elf proof search mechanism can be used to extract algorithmic content directly from the logic specifying the constraints.

We only consider assumptions involving identifiers (e.g., \( \text{bta} \ x : \tau [y : \varphi_\tau] \)) since the logic only allows discharging of assumptions of this form. For \( \Gamma = \{ \text{bta} \ x_1 : \tau_1 [y_1 : \varphi_{\tau_1}], \ldots, \text{bta} \ x_n : \tau_n [y_n : \varphi_{\tau_n}] \} \), the \( x_i \) are required to be pairwise distinct (similarly for the \( y_i \)). A static assumption (resp. dynamic assumption) is an assumption \( \text{bta} \ x : \tau [y : \varphi_\tau] \) where \( \varphi_\tau \) is static (resp. dynamic). \( \Gamma_s \) denotes a set of only static assumptions; \( \Gamma_d \) denotes a set of only dynamic assumptions.

A simple induction over the structure of deductions for \( \Gamma \vdash \text{bta} \ e : \tau [w : \varphi_\tau] \) shows that the relation between \( e \) and \( w \) is one-to-many, i.e., there may be many valid annotations of \( e \). As a consequence, a binding-time analysis satisfying these constraints has some flexibility in assigning correct annotations. In practice, one desires an analysis that gives as many eliminable directives (i.e., gives as many \( s \) indices) as possible.\(^4\) The constraint system is complete in the sense that one may always obtain a valid annotation of a type correct \( e \) by annotating all components as residual.

Finally, since the relation induced by \( \text{bta} \) is one-to-many from \( \Lambda \) to \( \Lambda_\kappa \), it is many-to-one (i.e., a function) from \( \Lambda_\kappa \) to \( \Lambda \). This is essentially an annotation forgetting function that removes directives and lift constructs.

The binding-time judgement is encoded in Elf as follows.

\[
\text{bta} : \text{exp} \rightarrow \{ \text{t : typ} \} \text{exp} \rightarrow \text{styp} \rightarrow \text{type}.
\]

The dependent function type (i.e., \( \{ \text{t : typ} \} \)) expresses the dependency of the indexed specialization type on the type of the expression.

Figure 10 presents the Elf encoding of the binding-time logic. The implicit universal quantification of the upper case variables captures the schematic nature of the rules. The rules for binding constructs (which involve hypothetical proofs in the premises) are encoded in Elf as proof constructors that take proofs of hypothetical judgements as arguments. Such proofs are represented as functions mapping proofs of assumption judgements to proofs of consequent judgements. The higher-order syntax representations requires that judgements involving identifiers be represented as schematic judgements (i.e., identifiers are \( \Pi \)-quantified). This is the case in rules \( \text{bta} \lambda_m s, \text{bta} \lambda_m d, \text{bta} \text{fix} s, \) and \( \text{bta} \text{fix} d \) where e.g., the judgement \( \text{bta} (E \ x) \ T2 (W \ y) \ P2 \) expresses that \( E \) and \( W \) may be instantiated to representations of terms with free occurrences of \( x \) and \( y \) respectively [19, Section 3.1].

4.2 Specialization

4.2.1 Natural deduction rules

Figures 11 and 12 present the specialization logic for \( \Lambda_\kappa \) terms.

- Figure 11 describes the evaluation of eliminable constructs. These rules correspond to the usual call-by-name "natural" or "deductive" operational semantics for \( \Lambda \) given in Figure 4.

- Figure 12 describes the reconstruction of residual constructs after subexpressions have been specialized. The rules for \( \lambda_m d \) and \( \text{fix} d \) are noteworthy because they introduce operations on open terms (e.g., bodies of \( \lambda_m d \) and \( \text{fix} d \) constructs). Following Hannan [15, p. 144], we specialize the body of a \( \lambda_m d \) (and \( \text{fix} d \)) under the assumption that the bound variable evaluates to itself.

\[^4\]We omit considering whether a term has a "best" annotation according to the logic. See the work on \( \lambda \)-mix [10, 11] for related discussions.

Figure 14: The Elf encoding of the specialization logic (dynamic and coercion constructs)
An alternative to introducing local assumptions for bound variables would be to add the axiom \( y \Psi_{\text{spec}} y \) (which states that all variables evaluate to themselves). However, this approach cannot be directly represented in Elf. Under the higher-order abstract syntax representation, the variables \( y \) are not objects in the Elf signature. The approach taken in Figure 12 seems the most natural with the higher-order abstract syntax representation.

- The final rules of Figure 12 coerce an eliminable numeral to a residual expression.

We write \( \Sigma \vdash w \Psi_{\text{spec}} a \) when \( w \Psi_{\text{spec}} a \) is derivable under undischarged assumptions \( \Sigma \). Intuitively, if \( \Sigma \vdash w \Psi_{\text{spec}} a \), then the specializer maps \( w \in \text{Terms}[\Lambda_0] \) to answer \( a \in \text{Terms}[\Lambda_0] \) in context \( \Sigma \). We only consider assumptions involving identifiers (e.g., \( y \Psi_{\text{spec}} y \)) since the logic only allows discharging of assumptions of this form. For \( \Sigma = \{ y_1 : \Psi_{\text{spec}} y_1, \ldots, y_n : \Psi_{\text{spec}} y_n \} \) the \( y_i \) are required to be pairwise distinct. \( \Sigma \) is compatible with \( \Gamma = \{ \text{bta } x_1 : \tau_1 [y_1 : \varphi_{\tau_1}], \ldots, \text{bta } x_n : \tau_n [y_n : \varphi_{\tau_n}] \} \) if \( \Sigma = \{ y_1 : \Psi_{\text{spec}} y_1, \ldots, y_n : \Psi_{\text{spec}} y_n \} \). It is easy to check that the relation induced by \( \Psi_{\text{spec}} \) is a partial function (given the constraints on assumptions above).

### 4.2.2 Elf encoding

Figures 13 and 14 give the Elf encoding of the specialization logic. The encoding techniques are similar to those used in the previous section. The specialization judgement specifies a binary relation (which is actually a partial function) on annotated terms \( \text{Sexp} \) and is encoded in Elf as follows.

\[
\text{spec} : \text{sexp} \rightarrow \text{sexp} \rightarrow \text{type}.
\]

In the rules \( \text{spec} \_\text{app} \_s \) and \( \text{spec} \_\text{fix} \_s \), we take advantage of the higher-order abstract syntax representation and use Elf application (\( i.e. \), \( \beta \)-reduction) to implement capture-free substitution.

### 4.2.3 Canonical terms of specialization

In the conventional deductive semantics for \( A \) in Section 3.3, one has numerals (\( e.g. \), \( 0, \infty \)) and \( \text{lam} x . c \) as canonical terms, \( i.e. \), these terms are the results of evaluation. This was formalized by the \text{val} judgement.

Intuitively, a specializer is part evaluator and part compiler. Therefore, the canonical terms of the specializer are numerals and \( \text{lam} y . w \) (corresponding to evaluation results), and completely residual terms or \text{code} (corresponding to compilation results). In a manner analogous to the formalization of \text{values} (canonical terms of evaluation), Figure 15 formalizes the notion of answers (canonical terms of specialization) by defining a judgement \( \text{ans } w : \varphi_{\tau} \).

We write \( A \vdash \text{ans } w : \varphi_{\tau} \) when \( \text{ans } w : \varphi_{\tau} \) is derivable under undischarged assumptions \( A \). \( A \) is compatible with \( \Gamma = \{ \text{bta } x_1 : \tau_1 [y_1 : \varphi_{\tau_1}], \ldots, \text{bta } x_n : \tau_n [y_n : \varphi_{\tau_n}] \} \) if \( A = \{ \text{ans } y_1 : \varphi_{\tau_1}, \ldots, \text{ans } y_n : \varphi_{\tau_n} \} \). Intuitively, if \( \text{ans } w : \varphi_{\tau} \) holds, then \( w \) is a canonical term of specialization type \( \varphi_{\tau} \). In particular, if \( \vdash \text{ans } w : \text{dyn} \), then \( w \) is completely residual.

In contrast with the \text{val} judgement of Section 3.3 which contained no notion of typing, the judgement \( \text{ans } w : \varphi_{\tau} \) relates a canonical term \( w \) to a particular specialization type \( \varphi_{\tau} \). We will need this additional information when stating the correctness of binding-time analysis in Section 6.1. As with the \text{val} judgement, the \text{ans} judgement admits answers that are not well-annotated. For example, \( \vdash \text{ans } \text{sc} (\text{lam} x . x) : \text{dyn}_{\tau} \) but there does not exist \( c \) and \( \tau \) such that \( \vdash \text{bta } c : \tau [\text{sc} (\text{lam} x . x) : \tau] \). Well-annotatedness of answers is expressed by using the binding-time judgement in conjunction with the answer judgement. Figure 16 gives the Elf encoding of the answer logic.

In Section 3.3, Proposition 1 showed that the value judgement \text{val} described the results of evaluation. An analogous proposition below shows that the answer judgement describes the results of specialization.

**Proposition 2** If \( \vdash w \Psi_{\text{spec}} a \) and \( \vdash \text{bta } c : \tau [w : \varphi_{\tau}] \), then \( \vdash \text{ans } a : \varphi_{\tau} \).

The proof of this proposition follows as a corollary of the mechanically verified proof of Theorem 1 in Section 6.

4.3 Partial evaluation

We outline how the logics above define offline partial evaluation using the following object term.

\[ e \overset{\text{def}}{=} \text{app} (\text{lam} \ x_1, \ \text{app} \ x_2 (\text{app} (\text{lam} \ x_3, \ x_1) \ x_0)) \]

The free variables \( x_0, x_2 \) represent input parameters. The assumptions \( \Gamma_s = \{ \text{bta} \ x_0 : \text{nat} [y_0 : \text{sta}] \} \) and \( \Gamma_d = \{ \text{bta} \ x_2 : \text{nat} \rightarrow \text{nat} [y_2 : \text{dyn}] \} \) identify \( x_0 \) of type \( \text{nat as known} \) and \( x_2 \) of type \( \text{nat as unknown} \). They also associate \( x_0 \) and \( x_2 \) with annotated language identifiers \( y_0 \) and \( y_2 \). The fact that \( \Gamma_s \cup \Gamma_d \vdash \text{bta} \ e \in \text{nat} [w : \text{dyn}] \)

where

\[ w \overset{\text{def}}{=} \text{app}_s (\text{lam}_s \ y_1, \ \text{app}_d \ y_2 (\text{lift} (\text{app}_s (\text{lam}_s \ y_3, \ y_2) \ y_1))) \]

expresses that a binding-time analysis may associate \( e \) with \( w \) based on assumptions \( \Gamma_s \cup \Gamma_d \).

To prepare for specialization, we supply known input via substitution.

\[ \Gamma_d \vdash \text{bta} \ e[x_0 := 0] : \text{nat} [w[y_0 := 0] : \text{dyn}] \]

Now taking \( \Sigma = \{ y_2 \ \psi_{\text{pec}} \ y_2 \} \) compatible with \( \Gamma_d \) (expressing that the dynamic parameter evaluates to itself), the specialization logic gives

\[ \Sigma \vdash w[y_0 := 0] \ \psi_{\text{pec}} \ \text{app}_d \ y_2 0_d. \]

Theorem 1 (correctness of binding-time analysis) of Section 6.1 tells us there exists \( e' \in \Lambda \) such that \( \Gamma_d \vdash \text{bta} \ e' \in \text{nat} [\text{app}_d \ y_2 0_d : \text{dyn}] \). As noted in Section 4.1, \( e' \) must be \( \text{app}_x 0 \) — the unannotated version of \( \text{app}_d \ y_2 0_d \). Theorem 3 (soundness of specialization) of Section 6.2 tells us that \( e[x_0 := 0] \) is convertible to \( e' \)

(denoted \( e[x_0 := 0] =_\Lambda e' \)) in the program calculus for \( \Lambda \). Thus, for all closed inputs \( d \in \Lambda \) of type \( \text{nat} \rightarrow \text{nat} \),

\[ e[x_0 := 0, \ x_2 := d] =_\Lambda e'[x_2 := d]. \]

This reflects the correctness criteria for partial evaluation given at the beginning of Section 4: running \( e \) on static input \( 0 \) and dynamic input \( d \) is operationally equivalent to running \( e' \) on \( d \).

5 Prototyping an Offline Partial Evaluator for \( \Lambda \)

5.1 Prototyping a binding-time analysis

The Elf encoding of the binding-time logic (see Figure 10) gives a prototype of the binding-time analysis. The following Elf query returns all the possible annotations that may be assigned to the example term of Section 3 (here we make \( \text{dyn} \) the specialization type of the entire term).\footnote{Some of the results of Elf evaluation are \( \alpha \)-converted for clarity.}

?- bta (app (lam [x1] lam [x2] app (lam [x3] x3) x1) z) (arrow nat nat) \ w \ dyn.

Solving...

\[ \overline{w} = \text{bapp} \ s \]
\[ (\text{blam} \ s \ (([y1:sexp] \text{blam} \ d \ ([y2:sexp] \text{bapp} \ s \ (\text{blam} \ s \ ([y3:sexp] \text{y3})) \ (\text{lift} \ y1)))) \]
\[ (\text{bz} \ s). \]

\[ \overline{w} = \text{bapp} \ s \]
\[ (\text{blam} \ s \ (([y1:sexp] \text{blam} \ d \ ([y2:sexp] \text{lift} \ (\text{bapp} \ s \ (\text{blam} \ s \ ([y3:sexp] \text{y3})) \ y1)))) \]
\[ (\text{bz} \ s). \]

There are actually twelve correct annotations; we show only the two above.

5.2 Prototyping a specializer

The Elf encoding of the specialization logic (see Figures 13 and 14) gives a prototype of the specializer. The following Elf query returns the result \( \Lambda \) of specializing the second annotated term above (there is only one answer since \( \text{spec} \) is a function).

22
\[ S : \text{spec} \ (\text{bapp} \ s) \]
\[ = \text{blam} \ s \ ([y_1 : \text{sexp}] \text{blam} \ d \ ([y_2 : \text{sexp}] \text{lift} \ (\text{bapp} \ s \ ([y_3 : \text{sexp}] \ y_3)) \ y_1)) \]
\[ \text{(bz s) A.} \]

Solving...

\[ A = \text{blam} \ d \ ([y_2 : \text{sexp}] \text{bz} \ d), \]

\[ S = \text{spec} \cdot \text{app} \cdot s \]
\[ = \text{spec} \cdot \text{lam} \cdot d \ ([y_2 : \text{sexp}] \text{[S:spec y2 y2]} \text{spec} \cdot \text{lift} \ (\text{spec} \cdot \text{app} \cdot s \text{ spec} \cdot z \cdot s \text{ spec} \cdot \text{lam} \cdot s)) \]
\[ \text{spec} \cdot \text{lam} \cdot s. \]

; no more solutions

In this query, we add the variable \( S \) which binds to the specialization deduction used to obtain \( A \).\(^6\)

6 Verifying an Offline Partial Evaluator for \( \Lambda \)

6.1 Binding-time analysis

A binding-time analysis is correct if it always produces consistent specialization directives. Directives are consistent if the specialization never “go wrong”. As described by Palsberg [27], a specialization may go wrong for two reasons: 1) it trusts a part of the program to be eliminable when in fact it is residual, and 2) it trusts a part of the program to be residual when in fact it is eliminable.

The specialization goes wrong for the first reason on \( \text{app} \cdot (\text{lam}_d \cdot x \cdot x) \cdot \theta \). In this case, it attempts evaluation using the rule \( \text{spec} \cdot \text{app} \cdot s \) (see Figure 11) but “hangs” (i.e., the result of specialization is undefined) since \( \text{lam}_d \cdot x \cdot x \) is not an eliminable abstraction. Similar problems may occur with the rule \( \text{spec} \cdot \text{lift} \) (e.g., if \( w \cdot \psi_{\text{spec}} \cdot 0_d \)).

The specialization goes wrong for the second reason on \( \text{app}_d \cdot (\text{lam}_d \cdot x \cdot x) \cdot \theta_d \). In this case, it attempts residualization using the rule \( \text{spec} \cdot \text{app} \cdot d \) and incorrectly produces an output program that is not completely residual (since \( \text{lam}_d \cdot x \cdot x \) is eliminable).

The property that the specialization never goes wrong (i.e., the binding-time analysis always yields consistent directives) is a generalization of the type-soundness property for standard type systems. To establish type-soundness, one typically proves a subject-reduction result showing that typing is maintained under evaluation. To establish consistency of directives, we prove that specialization typing is maintained under specialization. Furthermore, we show that specialization results are always answers of the appropriate specialization type, i.e., that the \( \text{ans} \) is always satisfied (as promised in Section 4.2).

This ensures that the specialization will not go wrong for the first reason. For example, in the rule \( \text{spec} \cdot \text{app} \cdot s \), the rule \( \text{blam} \cdot \text{app} \cdot s \) guarantees that \( w_0 \) always has specialization type \( \varphi_1 \rightarrow \varphi_2 \) and if \( w_0 \cdot \psi_{\text{spec}} \cdot a_0 \) then \( a_0 \equiv \text{lam}_d \cdot x \cdot w_0 \) since only appropriate answers are produced.

This also ensures that the specialization will not go wrong for the second reason. For example, in the rule \( \text{spec} \cdot \text{app} \cdot d \), the rule \( \text{blam} \cdot \text{app} \cdot d \) guarantees that \( w_0 \) always has specialization type \( \text{dyn} \) and if \( w_0 \cdot \psi_{\text{spec}} \cdot a_0 \) then \( a_0 \) must be completely residual (similarly for \( a_1 \)).

Theorem 1 (Correctness of binding-time analysis) If \( \Sigma \vdash w \cdot \psi_{\text{spec}} \cdot a \) and \( \Gamma_d \vdash \text{bla} \cdot e : \tau \cdot [w : \varphi_r] \) and \( \Sigma \) is compatible with \( \Gamma_d \), then there exists \( c' \in \Lambda \) such that \( \Gamma_d \vdash \text{bla} \cdot c' : \tau \cdot [a : \varphi_r] \) and \( A \vdash \text{ans} \cdot a : \varphi_r \) where \( A \) is compatible with \( \Gamma_d \).

Proof: For notational convenience, we write \( D :: J \) when \( D \) is a deduction of judgement \( J \) and state deduction rules in a linear format. For example, a specialization deduction that ends with the rule \( \text{spec} \cdot \text{app} \cdot d \) is written \( \text{spec} \cdot \text{app} \cdot d(S_0, S_1) :: \text{app}_d \cdot w_0 \cdot w_1 \cdot \psi_{\text{spec}} \cdot \text{app}_d \cdot a_0 \cdot a_1 \) where \( S_i :: w_i \cdot \psi_{\text{spec}} \cdot a_i \) (\( i = 1, 2 \)). The notation is somewhat imprecise since we do not use an explicit discharge function for assumptions [19, Section 4.1]. However, the Elf encoding makes matters sufficiently clear.

For the theorem hypotheses, let \( S :: w \cdot \psi_{\text{spec}} \cdot a \) and \( B :: \text{bla} \cdot e : \tau \cdot [w : \varphi_r] \). We show an effective method for constructing deductions \( C :: \text{bla} \cdot c' : \tau \cdot [a : \varphi_r] \) and \( D :: \text{ans} \cdot a : \varphi_r \) where the compatibility constraints on undischarged assumptions are satisfied. The proof proceeds by induction on the number of deductions \( S \) and \( B \),

\( ^{\text{Note that the order of arguments to the deduction constructors is the reverse of what one might expect since we use } \Leftarrow \text{ (instead of } \Rightarrow) \text{ in the encodings of the bindings, time and specialization logics.} \)
i.e., the method is primitive recursive. Although this primitive recursive method cannot be represented in Elf as a function (since it is not schematic), it can be represented as a relation via the following judgement.

\[ \text{t1 : spec W A -> bta E T W P -> bta E' T A P -> ans A P -> type.} \]

Each case of the constructive proof is formalized as a rule for the t1 judgement. Below we show three illustrative cases (each increasing in complexity).

case \( S = \text{spec}\_z\_s :: s \) \( \cup \text{spec} \ 0 \), and \( B = \text{bta}\_z\_s :: \text{bta} 0 : \text{nat} [0 : \text{sta}]; \)

The required deductions are \( \text{bta}\_z\_s :: \text{bta} 0 : \text{nat} [0 : \text{sta}] \) and \( \text{ans}\_z\_s :: \text{ans} 0 : \text{sta} \). This is formalized by the following axiom.

\[ \text{t1}_z\_s : \text{t1 (spec}\_z\_s) (\text{bta}\_z\_s) (\text{bta}\_z\_s) (\text{ans}\_z\_s). \]

case \( S = \text{spec}_d d(S_0, S_1) :: \text{app}_d w_0 w_1 \cup \text{spec}_d a_0 a_1, \)

\( B = \text{bta}_d d d(B_0, B_1) :: \text{bta}_d d d d(C_0, C_1) : \text{t}\_d [\text{app}_d w_0 w_1 : \text{dyn}]. \)

Applying the inductive hypothesis to \( S_0 \) and \( B_0 \) gives deductions \( C_0 :: \text{bta} c'_0 : \tau_1 \rightarrow \tau_2 [a_0 : \text{dyn}] \) and \( D_0 :: \text{ans} a_0 : \text{dyn} \). Applying the inductive hypothesis to \( S_1 \) and \( B_1 \) gives deductions \( C_1 :: \text{bta} c'_1 : \tau_1 \rightarrow \tau_2 [a_1 : \text{dyn}] \) and \( D_1 :: \text{ans} a_1 : \text{dyn} \). The required deductions are \( \text{bta}_d d d (C_0, C_1) \) and \( \text{ans}_d d d (D_0, D_1) \). This is formalized by the following rule (the arguments to the proof constructors appear in reverse order (e.g., \( \text{spec}_d d S_1 S_0 \) instead of \( \text{spec}_d d S_0 S_1 \)) due to the use of \( \leftarrow \) (instead of \( \rightarrow \)) in the encodings of binding-time and specialization logic).

\[ \text{t1}\_d : \text{t1 (spec}_d d S_1 S_0) (\text{bta}_d d d B_1 B_0) (\text{bta}_d d d C_1 C_0) (\text{ans}_d d d D_0 D_1) \]

\[ \leftarrow \text{t1} S_0 B_0 C_0 D_0 \]

\[ \leftarrow \text{t1} S_1 B_1 C_1 D_1. \]

In operational terms, the inductive hypotheses are manifested as recursive calls to the function represented by \( \text{t1} \).

\[ \text{case} S = \text{spec}_d d d(S_0, S_1) :: \text{app}_d w_0 w_1 \cup \text{spec}_d a \]

\( B = \text{bta}_d d d d(B_0, B_1) :: \text{bta}_d d d d d(C_0, C_1) : \text{t}\_d [\text{app}_d w_0 w_1 : \varphi_2]. \)

Applying the inductive hypothesis to \( S_0 \) and \( B_0 \) gives deductions \( C'_0 :: \text{bta} c'_0 : \tau_1 \rightarrow \tau_2 [a_0 : \varphi_1 \rightarrow \varphi_2] \) and \( D_0 :: \text{ans} a_0 : \varphi_1 \rightarrow \varphi_2 \). An examination of the \( \text{ans} \) rules (Figure 15) reveals that \( a_0 \equiv \text{lam}_s y, w'_0. \)

Then, an examination of the axiomatization of the \( \text{bst} \) judgement (Figure 9) shows that we must have \( C'_0 = \text{bta}_d d d d\text{Jam}_s (C_0 :: \text{bta} c'_0 : \tau_1 [w'_0 : \varphi_2]) :: \text{bta}_d \text{lam}_s x. c' :: \tau_1 \rightarrow \tau_2 [\text{lam}_s y, w'_0 : \varphi_1 \rightarrow \varphi_2] \) where the undischarged assumptions of \( C_0 \) include \( \text{bta} x : \tau_1 [y : \varphi_1]. \) A simple substitution lemma (which we omit) allows us to replace each of these assumptions in \( C'_0 \) with the deduction \( B_1 :: \text{bta} c_1 : \tau_1 [w_1 : \varphi_1] \) to obtain a deduction \( B'_0 :: \text{bta} c'_0 [x := c_1] : \tau_2 [w'_0[y := w_1] : \varphi_2]. \) Applying the inductive hypothesis to \( S_1 \) and \( B_2 \) gives the required deductions \( C :: \text{bta} c' : \tau_1 [a : \varphi_2] \) and \( D :: \text{ans} a : \varphi_2. \) This is formalized as follows.

\[ \text{t1}\_d : \text{t1 (spec}_d d S_1 S_0) (\text{bta}_d d d B_1 B_0) C D \]

\[ \leftarrow \text{t1} S_0 B_0 (\text{bta}_d \text{lam}_s C_0) D_0 \]

\[ \leftarrow \text{t1} S_1 (\text{C} \_ \_ B_1) C D. \]

The “examination of the rules” (that told us deduction \( C'_0 \) must have \( \text{bta}_d \text{Jam}_s \) as its last rule) is captured by matching (i.e., \( \text{bta}_d \text{lam}_s C_0 \)). The required substitution lemma appears for free due to the higher-order abstract syntax representation and the Transitivity derived rule of the LF calculus [19, Section 2.3]; it is captured by \( \text{C} \_ \_ B_1 \). The underscores correspond to the terms \( c_1 \) and \( w_1 \) above. Using the underscores and letting Elf reconstruct allows us to encode the rule more concisely.

The complete set of rules is given in Appendix A.

The following Elf query illustrates the function induced by the \text{t1} rules. Given the specialization deduction \( S \) of Section 5.2 and a binding-time deduction for the term being specialized (i.e., the second annotated term of Section 5.1), \( \text{t1} \) constructs a binding-time deduction \( C \) for the specialization answer as well as an answer deduction \( D \) proving that the answer is completely residual.
?- t1 (spec_app_s
(spec_lam_d [y2:sexp] [S:spec y2 y2] spec_lift (spec_app_s spec_z_s spec_lam_s))
spec_lam_s)
(spec_z_s spec_lam_s)
(bta_app_s bta_z_s
(bta_lam_s [x1:exp] [y1:exp] [B1:bta x1 nat y1 sta]
bta_lam_d [x2:exp] [y2:sexp] [B2:bta x2 nat y2 dyn]
bta_lift
(bta_app_s B1
(bta_lam_s [x3:exp] [y3:sexp] [B3:bta x3 nat y3 sta] B3)))
C D.
Solving...

D = ans_lam_d [y2:sexp] [B2:ans y2 dyn] ans_z_d,
C = bta_lam_d [x2:exp] [y2:sexp] [B2:bta x2 nat y2 dyn] bta_z_d.

Elf type-checking mechanically verifies that deductions C and D are well-formed when they exist. However, verification that such deductions always exist (i.e., that t1 is total) cannot be captured in Elf. This phase of verification (called schema checking) must be done by hand, although its automation is the subject of current research [32]. Our definition makes t1 total because we give a rule for each possible pair of spec and bta rules (giving primitive recursive structure). In addition, the deduction of answer judgements tell us that matching is used (in rules t1_app_s and t1_lift) only when it will always succeed.

6.2 Soundness of specialization

A specializer is sound if its steps describe a meaning preserving transformation on the unannotated object program. Specifically, if (a) e1 is the unannotated version of the program to be specialied (with the static data already supplied), and (b) e2 is the unannotated version of the result of specialization, then a sound specializer should guarantee that e1 and e2 are operationally equivalent (as defined in Section 3.3).

This ensures that e1 and e2 will behave the same under evaluation when dynamic data is supplied. Specifically, for all dynamic data d such that T ⊢ tp e1[x := d] : nat and T ⊢ tp e2[x := d] : nat, e1[x := d] ≈ e2[x := d]. The last claim follows since the substitution [x := d] can be represented with the context app(lam x.[])[d] and the fact that ≈ is easily shown to be a congruence.

We prove the operational equivalence of e1 and e2 by appealing to a program calculus for Λ (i.e., an equational theory for deducing operational equivalences). Gunter [14, Chapter 4] gives a calculus for PCE, and Figure 17 recasts the calculus in our setting. e1 =_Λ e2 is the judgement expressing convertibility in the calculus. The rules are generally the expected ones for call-by-name. However, note the use of the judgement eval in the rules conv-prsc and conv-ifsc. This reflects the strictness of the primitive operation pr and the strictness of the conditional if0 in the test position. Appendix B.1 gives the Elf encoding of the calculus. It is similar to the encoding given by Pfennig for the pure untyped λ-calculus [30].

The following theorem expresses the soundness of the calculus for reasoning about Λ operational equivalences.

Theorem 2 (Soundness of calculus) For all e1, e2 ∈ Λ such that T ⊢ tp e1 : τ and T ⊢ tp e2 : τ,

\[ e_1 =_\Lambda e_2 \implies e_1 \approx e_2. \]

Existing techniques for proving the theorem are fairly involved. For example, Gunter [14] appeals to an adequacy result connecting the operational semantics and a model. Other techniques use co-induction principles [12]. Unfortunately, it seems impossible to encode any of these techniques in Elf (Section 8 discusses the encoding of these techniques in other frameworks).

The inability to encode the proof in Elf does not seem detrimental to our approach. Historically, one of the reasons for introducing for a program calculus is to avoid repeated appeals to direct proofs of operational equivalences and reason instead using the simple rules of the calculus. The appropriateness of this approach is underscored by the situation we face here — it is much easier to encode a proof that appeals to the calculus.

The following theorem captures the fact that the unannotated object program e is operationally equivalent to the unannotated specialization result e'.

25
\[\begin{align*}
\text{conv}_\beta & : \quad \text{app} (\text{lam} \ x, e_0) \ e_1 =_\Lambda e_0 \ [x := e_1] \\
\text{conv}_\text{fix} & : \quad \text{fix} \ x, e =_\Lambda e [x := \text{fix} \ x, e] \\
\text{conv}_\text{prz} & : \quad \text{pr} \ 0 =_\Lambda 0 \\
\text{conv}_\text{prsc} & : \quad \frac{\text{val} \ e}{\text{pr} (\text{sc} \ e) =_\Lambda e} \\
\text{conv}_\text{ifz} & : \quad \text{if} 0 \ e_2 \ e_3 =_\Lambda e_2 \\
\text{conv}_\text{ifsc} & : \quad \frac{\text{val} \ e}{\text{if} 0 (\text{sc} \ e) \ e_2 \ e_3 =_\Lambda e_3} \\
\text{conv}_\text{refl} & : \quad e =_\Lambda e \\
\text{conv}_\text{sym} & : \quad \frac{e_2 =_\Lambda e_1}{e_1 =_\Lambda e_2} \\
\text{conv}_\text{trans} & : \quad \frac{e_1 =_\Lambda e_2 \ e_2 =_\Lambda e_3}{e_1 =_\Lambda e_3} \\
\text{conv}_\text{sc} & : \quad \frac{e =_\Lambda e'}{\text{sc} \ e =_\Lambda \text{sc} \ e'} \\
\text{conv}_\text{pr} & : \quad \frac{e =_\Lambda e'}{\text{pr} \ e =_\Lambda \text{pr} \ e'} \\
\text{conv}_\text{ifL1} & : \quad \frac{e_1 =_\Lambda e_1'}{\text{if} 0 \ e_1 \ e_2 \ e_3 =_\Lambda \text{if} 0 \ e_1' \ e_2 \ e_3} \\
\text{conv}_\text{ifL2} & : \quad \frac{e_2 =_\Lambda e_2'}{\text{if} 0 \ e_1 \ e_2 \ e_3 =_\Lambda \text{if} 0 \ e_1 \ e_2' \ e_3} \\
\text{conv}_\text{ifL3} & : \quad \frac{e_3 =_\Lambda e_3'}{\text{if} 0 \ e_1 \ e_2 \ e_3 =_\Lambda \text{if} 0 \ e_1 \ e_2 \ e_3'} \\
\text{conv}_\text{lamL} & : \quad \frac{e =_\Lambda e'}{\text{lam} \ x, e =_\Lambda \text{lam} \ x, e'} \\
\text{conv}_\text{appL0} & : \quad \frac{e_0 =_\Lambda e_0'}{\text{app} e_0 e_1 =_\Lambda \text{app} e_0 e_1} \\
\text{conv}_\text{appL1} & : \quad \frac{e_1 =_\Lambda e_1'}{\text{app} e_0 e_1' =_\Lambda \text{app} e_0 e_1'}
\end{align*}\]

Figure 17: Program calculus for $\Lambda$
Theorem 3 (Soundness of specializer) If $\Sigma \vdash w\ \psi_{spc}\ a$ and $\Gamma_d \vdash bta\ c : \tau[w;\varphi_r]$ and $\Sigma$ is compatible with $\Gamma_d$, then there exists $e' \in \Lambda$ such that $\Gamma_d \vdash bta\ e^! : \tau[a;\varphi_r]$ and $e =_\Lambda e'$.

Proof: To formalize the proof, we construct a function (via a relation as in Theorem 1) which builds a deduction showing $e$ converts to $e'$.

$$t3 : \text{spec } \Lambda\ A \to \text{bta } E\ T\ W\ P \to \text{bta } E'\ T\ A\ P \to \text{ans } A\ P \to \text{conv } E\ E' \to \text{type}.$$  

The $t3$ judgement expresses a function which takes two proofs as input: a proof of $\text{spec } \Lambda\ A$ and a proof of $\text{bta } E\ T\ W\ P$. The output judgement $\text{bta } E'\ T\ A\ P$ acts as the unannotating function from $\Lambda_{be}$ terms $A$ to $\Lambda$ terms $E'$ (see Section 4.1.3).

The output proof of $\text{ans } A\ P$ is necessary for extracting value deductions to be used in the $\text{conv}_{prsc}$ and $\text{conv}_{jsfc}$ rules of the calculus. This requires a small lemma — essentially stating that if the specialization type $P$ is static, then dropping the annotations on the answer $A$ yields a value. In other words, given a proof $\text{bta } E\ T\ W\ P$, a proof $\text{ans } W\ P$ that $W$ is a value, and a proof that $P$ is static, we can construct a proof that the de-annotation of $W$ (given by $E$) is a value. This is formalized with the following judgement.

$$\text{ans_to_val } : \text{bta } E\ T\ W\ P \to \text{ans } W\ P \to \text{static } P \to \text{val } E \to \text{type}.$$  

This proof is simple and omitted. The Elf encoding is given in Appendix B.2 along with the encoding of predicates describing static and dynamic specialization types.

Finally, the $\text{conv } E\ E'$ judgement expresses the desired property that $E$ converts to $E'$. A strategy similar to the one used in the proof of Theorem 1 given the rules defining $t3$ (see Appendix B.3).

Note that by including $\text{bta } E'\ T\ A\ P$ and $\text{ans } A\ P$ as we generate the deduction of $\text{conv } E\ E'$, we are in essence re-proving Theorem 1. An alternative approach would be to use Theorem 1 to justify some of the steps in the proof below. This would be manifested in the Elf encoding as “calls” to the goal represented by the $t1$ judgement. We choose the formalization below to simplify the presentation.

7 Related work

Despeyroux first emphasized using deductive systems to define transformations [8]. She specified a compiler, and source and target language semantics using deductive systems. The specifications were executed via encodings into Typol. Informal proofs of correctness were given as relations between deductions. However, these proofs could not be formalized in Typol because it does not support the direct manipulation of its own deductions.

Hannan and Pfening [18] improved upon this by formalizing similar proofs of correctness in Elf. Elf (unlike e.g., Typol and $\lambda$-Prolog) supports the direct manipulation of its own deductions. Furthermore, Elf type checking mechanically verifies that deductions corresponding to correctness proofs are well-formed. Other work using Elf to encode operational semantics includes Michaylov and Pfening’s encoding of call-by-value natural semantics and associated meta-theory for the language Mini-ML [23], Pfening’s representation of a Church-Rosser proof [30], Hannan’s encoding of a type system for closure conversion [16], and Niss and the author’s representation of the correctness proofs for the familiar translation of call-by-name to call-by-value using thunks [26].

Despeyroux [8, Section 8], and Hannan and Pfening [18, Section 7], suggested that their methods could be used to specify “mixed computation” and partial evaluation, respectively. Hannan and Miller [17] carried out Despeyroux’s suggestion: they use deductive systems encoded in $\lambda$-Prolog to obtain executable specifications of mixed computation (in their work, “mixed computation” = non-deterministic on-line partial evaluation).

Our contributions include using deductive systems to specify program specialization directed by type-based analysis. Moreover, we adapt the techniques of Hannan and Pfening [18], and Michaylov and Pfening [23] to mechanically verify correctness.

In doing so, we obtain verified proofs similar in scope to the ones given by Gomard and Jones [10, 11] for $\lambda$-mix. Their denotational meta-language is significantly more complex than our logic-based meta-language and it is unlikely that the proofs there could be formalized or mechanically verified to the extent that we have done here. However, it must be noted that one of their goals was self-application. Relying on the similarity between their meta-language and object-language, they obtain an object-language specification of the partial evaluator

27
(giving self-applicability) by a fairly easy (though informal and unverified) translation from the meta-language specification. In our setting this is more difficult since the character of our meta-language (logical) is quite different from our object language (functional).

Building upon the work of Gomard, Jones, and Mogensen, Palsberg [27] and Wand [37] give detailed presentations of the correctness of binding-time analysis. Palsberg presents a generalization of Gomard and Jones criteria [11] for consistent binding-time annotations. Wand studies Mogensen's self-applicable partial evaluator [24] for the pure \( \lambda \)-calculus. His binding-time analysis is essentially the same as Gomard and Jones's, as well as the one presented here. Wand's goals with respect to correctness of the analysis and specializer are more ambitious than those here, because his correctness criteria is strong enough to specify the behavior of the partial evaluator when self-applied.

It would be interesting to see to what extent the meta-theory used by Palsberg and Wand could be formalized in Elf. In particular, once Wand has established the correctness results for an interpreter and partial evaluator, his proofs for the Futamura projections have a simple calculational style (based on equational reasoning). The proofs follow the same steps as the "Mix equations" [20, Chapter 1] which are often used to reason about the results of self-application. We are currently investigating how these reasoning principles can be formalized (e.g., to obtain a "Mix equational theory") and encoded in LF.

In recent work, Davies and Pfenning [7] give a type system for expressing staged computation based on the intuitionistic modal logic S4. They have implemented the type system and a portion of the associated correctness proofs in Elf.

Our work focuses on partial evaluation of functional programs, but similar techniques can be applied to imperative languages as well. Blazy and Facon [2] specify a simple specializer for FORTRAN using natural semantics, and derive a prototype from the specification using the Centaur programming environment. However, their correctness proofs are not formalized since the Centaur environment is not oriented toward this purpose. Bertot and Fraer [1] show how similar correctness proofs (for a specializer for an imperative language) can be formalized and mechanically checked using Coq.

8 Conclusion

8.1 Summary

We have specified the main components of a simple offline partial evaluator (i.e., binding-time constraints and a program specializer) using natural-deduction style logics. These specifications were formalized by encoding them in LF. Prototypes were obtained directly from the formal specifications using Elf. We formalized and mechanically verified a significant portion of the meta-theory of offline partial evaluation (e.g., correctness of binding-time analysis and soundness of the specializer) via meta-programming in Elf. A certain degree of synergy is obtained by using the declarative formalism of deductive systems: one may specify, prototype and mechanically verify correctness via meta-programming — all within a single framework.

8.2 Assessment

Using deductive systems to specify analyses and transformations: The simplicity of the specifications stems from their declarative nature (which allows inessential algorithmic details and model theory to be avoided). This does not mean that other formalisms such as denotational semantics are not useful. There are certainly situations where the extra reasoning capabilities offered by model theory are beneficial. However, it seems that in many applications — particularly in the area of program specialization — these extra capabilities are never utilized and other styles of formalization such as the ones used here may be more appropriate.

Using LF as a meta-language for defining specifications: Using a formal meta-language such as LF forces one to be precise, and such precision usually lends clarity to presentations. However, the rigidity of LF almost demands that one cast specifications as natural-deduction-style logics and use higher-order abstract syntax. This style of logic may not be appropriate in all situations. In addition, it would be interesting to see how our specifications and proofs would be formalized in other logical frameworks. Recent work suggests that it may be possible to generate program analyses from formal specifications. LF stands as a possible meta-language for formalizing such specifications.
Using Elf to obtain executable specifications: We found Elf particularly useful for prototyping the binding-time analysis. It should be investigated if this scales up to more complicated type-based analyses that use conjunctive types and more general forms of subtyping. More complex specifications may well be prone to looping due to the simplistic depth-first search strategy used by Elf. However, we have successfully used the techniques presented here to prototype a more complex higher-order version of the multi-level binding-time analysis of Glick and Jørgensen [9].

Using Elf to mechanically verify correctness: It seems possible to use these techniques to verify other forms of program specialization. For example, if one takes the view that an annotated program is its own generating extension, the techniques here are very close to what one would use to verify the correctness of a hand-written cogen [20]. It remains to be seen if these techniques scale up to more robust forms of partial evaluation that include sophisticated folding strategies. One approach might be to use Sand’s calculus for sound fold/unfold transformations [34].

The logic of Elf was not strong enough to encode the calculus soundness proof (see Theorem 2). More generally, the induction principles as required in the proofs of Theorems 1 and 3 could not be completely formalized. This manifested itself in the inability to mechanically guarantee the totality of the functions (defined as relations) representing the constructive proofs. Frameworks based on stronger logics (such as Isabelle-HOL and Isabelle-ZF [28], HOL [13], and Coq) can overcome these problems. Nipkow [25] has used Isabelle-HOL to encode a large portion of the theory given in Winkels’s semantics textbook [39]. Similar techniques would be used in formalizing the calculus-soundness proof using model theory. Collins [4] has used HOL to encode a theory of bi-similarity for higher-order functional language. This could easily be extended to prove the soundness of the calculus using coinduction techniques. Finally, the forthcoming thesis of Welinder [38] contains a formalization of various principles required for reasoning about specialization of first-order functional programs.

Using stronger logics leads to tradeoffs. Proofs become much more involved (as formalization is more complete). Prototypes are harder to obtain directly from specifications.

Acknowledgements

John Haman deserves special acknowledgement for his careful reading of earlier drafts of the paper. His detailed comments helped clarify the presentation. Thanks to Frank Pfenning for several enlightening conversations and for making his material on Elf easily accessible. Thanks to Olivier Danvy for his encouragement and comments on various drafts. Robert Glick, Kristian Nielsen, Henning Niss, Dave Savds, and other members of the DIKU TOPPS group gave valuable feedback and support. Thanks to the PLILP 95 referees for helpful comments.
