Termination Analysis and Specialization-Point Insertion in Off-line Partial Evaluation

ARNE JOHN GLENSTRUP and NEIL D. JONES
DIKU, University of Copenhagen

Recent research suggests that the goal of fully automatic and reliable program generation for a broad range of applications is coming nearer to feasibility. However, several interesting and challenging problems remain to be solved before it becomes a reality. Solving them is also necessary, if we hope ever to elevate software engineering from its current state (a highly-developed handicraft) into a successful branch of engineering, capable of solving a wide range of new problems by systematic, well-automated and well-founded methods.

A key problem in all program generation is termination of the generation process. This paper focuses on off-line partial evaluation and describes recent progress towards automatically solving the termination problem, first for individual programs, and then for specializers and "generating extensions," the program generators that most offline partial evaluators produce.

The technique is based on size-change graphs that approximate the changes in parameter sizes at function calls. We formulate a criterion, bounded anchoring, for detecting parameters known to be bounded during specialization: a bounded parameter can act as an anchor for other parameters. Specialization points necessary for termination are computed by adding a parameter that tracks call depth, and then selecting a specialization point in every call loop where it is unanchored. By generalizing all unbounded parameters, we compute a binding-time division which together with the set of specialization points guarantees termination.

Contributions of this paper include a proof, based on the operational semantics of partial evaluation with memoization, that the analysis guarantees termination; and an in-depth description of safety of the increasing size approximation operator required for termination analysis in partial evaluation.

Initial experiments with a prototype shows that the analysis overall yields binding-time divisions that can achieve a high degree of specialization, while still guaranteeing termination.

The paper ends with a list of challenging problems whose solution would bring the community closer to the goal of broad-spectrum, fully automatic and reliable program generation.

Categories and Subject Descriptors: F.3.2 [Logics and Meanings of Programs]: Semantics of Programming Languages—partial evaluation; program analysis; F.3.3 [Logics and Meanings of Programs]: Studies of Program Constructs—program and recursion schemes; I.2.2 [Artificial Intelligence]: Automatic Programming—program transformation; D.1.2 [Programming Techniques]: Automatic Programming; F.3.1 [Logics and Meanings of Programs]: Specifying and Verifying and Reasoning about Programs—specification techniques; D.3.3 [Programming Languages]: Language Constructs and Features—recursion; D.3.4 [Programming Languages]: Processors—optimization; compilers; interpreters

General Terms: Algorithms, experimentation, theory

Additional Key Words and Phrases: Binding-time analysis, quasitermination, size-change graphs, termination

1. ON PROGRAM GENERATION

Program generation is a rather old idea, dating back to the 1960s and seen in many forms since then. Instances include code templates, macro expansion, conditional assembly and the use of if-defs, report generators, partial evaluation/program specialization [Consel and Danvy 1993, Jones et al. 1993, Lloyd and Shepherdson 1991], domain-specific languages (at least, those compiled to an implementation language) [Hudak 1996], program transformation [Burstall and Darlington 1977, Chin et al. 1998], Gallagher and Bruynooghe 1990], and both practical and theoretical work aimed at generating programs from specifications [Hudak 1996, Kieburz et al. 1996].

Recent years have seen a rapid growth of interest in generative, automatic approaches to program management, updating, adaptation, transformation, and evolution, e.g., [Kieburz et al. 1996, McNamee et al. 2001, Taha 2000]. The motivations are well known: persistence of the "software crisis" and dreams of achieving industrial-style automation, automatic adaptation of programs to new contexts, and automatic optimization.

The overall goal is to increase efficiency of software production by making it possible to write fewer but more abstract or more heavily parameterized programs. Ideally, one would like to transform a problem specification automatically into a solution in program form. Benefits of such an approach would include increased reliability in software production: The software developer can debug/test/verify a small number of high-level, compact programs or specifications; and then generate from these as many machine-near, efficiently executable, problem-specific programs as needed, all guaranteed to be faithful to the specification from which they were derived.

1.1 What are programs generated from?

On a small scale, programs can be generated from problem parameters (e.g., device characteristics determine the details of a device driver). Ideally, and on a larger scale, programs could be generated from user-oriented problem descriptions or specifications. Dreams of systematically transforming specifications into solutions were formulated in the 1970s by Dijkstra, Gries, Hoare, Manna, etc.

This approach has been tried out in real-world practice and some serious problems have been encountered. First, it is very hard to see whether a program actually solves the problem posed by a description or specification. Second, it seems impossible for specifications of manageable size to be complete enough to give the "whole picture" of what a program should do for realistic problem contexts. While there have been recent and impressive advances in bridging some gaps between specifications and programs by applying model-checking ideas to software [Corbett et al. 2000], they are incomplete: the specifications used nearly always describe only certain misbehaviors that cannot be accepted, rather than total program correctness.

Executable specifications. It has proven to be quite difficult to build a program from an unexecutable, nonalgorithmic specification, e.g., expressed in first-order or temporal logic. For realistic problems it is often much more practical to use an executable specification. Such a specification is, in essence, also a program; but is written on a higher level of abstraction than in an implementation language, and
usually has many “don’t-care” cases.

Consequence: Many examples of “generative software engineering” or “transforming specifications into programs” or “program generation” can be thought of as transformation from one high-level program (specification-oriented) to another lower-level one (execution-oriented). In other words, much of generative software engineering can be done by (variations on) compilation or program transformation. This theme has been seen frequently, first in early compilers, then in use of program transformation frameworks for optimizations, then in partial evaluation, and more recently in multi-stage programming languages.

Partial evaluation for program generation. This paper concerns some improvements needed in order to use partial evaluation as a technology for automatically transforming an executable problem specification into an efficient stand-alone solution in program form. There have been noteworthy successes and an enormous literature in partial evaluation: see Sestoft 2001 and the PEPM series, as well as the Asia-PEPM and SAIG conferences. However, its use for large-scale program generation has been hindered by the need, given an executable problem specification, to do “hand tuning” to ensure termination of the program generation process: that the partial evaluator will yield an output program for every problem instance described by the current problem specification.

1.2 Fully automatic program transformation: an impossible dream?

Significant speedups have been achieved by program transformation on a variety of interesting problems. Pioneers in the field include Bird, Boyle, Burstall, Darlington, Dijkstra, Gries, the Kestrel group, Meertens and Paige; more recent researchers include De Moor, Liu and Pettorossi. As a result of this work, some significant common principles for deriving efficient programs have become clear:

—Optimize by changing the times at which computations are performed (code motion, preprocessing, specialization, multi-staged programming languages [Aho et al. 1986] Consl and Danvy 1993 [Krzan et al. 2001] Jones et al. 1993; Hatchet et al. 1999; Laba 1999a; Laba et al. 2001 [Laba and Sheard 2000]).

—Don’t solve the same sub-problem repeatedly. A successful practical example is the XSB logic programming system [Sagonas et al. 1994], based on memoization: Instead of recomputing results, store them for future retrieval when first computed.

—Avoid multiple passes over same data structure (tupling, deforestation [Burstall and Darlington 1977; Chin et al. 1998; Gluck and Sorensen 1996; Wadler 1988]).

—Use an abstract, high-level specification language. SETL [Cai et al. 1991] is a good example, with small mathematics-like specifications (sets, tuples, finite mappings, fixpoints) that are well-suited to automatic transformation and optimization of algorithms concerning graphs and databases.

The pioneering results already obtained in program transformation are excellent academic work that include the systematic reconstruction of many state-of-the-art fundamental algorithms seen in textbooks. Such established principles are being used to develop algorithms in newer fields, e.g., computational geometry and bio-

computation. On the other hand, these methods seem ill-suited to large-scale, heterogeneous computations: tasks that are broad rather than deep.

Summing up. Program transformation is a promising field of research but its potential in practical applications is still far from being realized. Much of the earlier work has flavor of a "fine art," practiced by highly gifted researchers on one small program at a time. Significant automation has not yet been achieved for the powerful methods capable of yielding superlinear speedups. The less ambitious techniques of partial evaluation have been more completely automated, but even there, termination remains a challenging problem.

This problem setting defines the focus of this paper. For simplicity, in the remainder of this article we use a simple first-order functional language.

1.3 Requirements for success in generative software engineering

The major bottlenecks in generative software engineering have to do with humans. For example, most people cannot and should not have to understand automatically generated programs—e.g., to debug them—because they did not write them themselves. A well-known analogy: the typical user does not and probably cannot read the output of parser generators such as Yacc and Lex, or the code produced by any commercial compiler.

If a user is to trust programs he/she did not write, a firm semantic basis is needed, to ensure that user intentions match the behavior of the generated programs. Both intentions and behavior must be clearly and precisely defined. How can this be ensured?

First, the source language or specification language must have a precisely understood semantics (formal or informal; but tighter than, say, C++), so the user can know exactly what was specified. Second, evidence (proof, testing, etc.) is needed that the output of the program generator always has the same semantics as specified by its input. Third, familiar software quality demands must be satisfied, both by the program generator itself and the programs that it generates.

Desirable properties of a program generator thus include:

(1) High automation level. The process should
—accept any well-formed input, i.e., not commit generation-time failures like "can't take tail of the empty list"
—issue sensible error messages, so the user is not forced to read output code when something goes wrong

(2) The code generation process should
—terminate for all inputs
—be efficient enough for the usage context, e.g., the generation phase should be very fast for run-time code generation, but need not be for highly-optimizing compilation

(3) The generated program
—should be efficient enough for the usage context, e.g., fast generated code in a highly-optimizing compilation context
—should be of predictable complexity, e.g., not slower than executing the source specification

—should have an acceptable size (no code explosion)
—may be required to terminate.

1.4 On the meaning of ‘automatic’ in program transformation

The goals above are central to the field of automatic program transformation. Unfortunately, this term seems to mean quite different things to different people, so we now list some variations as points on an “automation” spectrum:

(1) Hand work, e.g., program transformation done and proven correct on paper by gifted researchers. Examples: recursive function theory [Peter 1976], work by McCarthy and by Bird.

(2) Interactive tools for individual operations, e.g., call folding and unfolding. Examples: early theorem-proving systems, the Burstall-Darlington program transformation system [Burstall and Darlington 1977].

(3) Tools with automated strategies for applying transformation operations. Human interaction to check whether the transformation is “on target.” Examples: Chin, Khoo, Liu [Chin et al. 1998; Liu 2000].

(4) Hand-placed program annotations to guide a transformation tool. Examples: Chambers’ and Engeler’s DvC and Tick C [Grant et al. 2000; Poletto et al. 1999]. After annotation, transformation is fully automatic, requiring no human interaction.

(5) Tools that automatically recognize and avoid the possibility of nontermination during program transformation, e.g., homeomorphic embedding. Examples: Sørensen, Glück, Leuschel [Leuschel 1993; Sørensen and Glück 1995].

In the following we use the term “automatic” mostly with the meaning of point (6).

This paper’s goal is automatically to perform the annotations that will ensure termination of program specialization. We will ignore issues concerning code duplication, elimination and reordering, as they are important issues in themselves treated elsewhere [Jones et al. 1993].

2. PARTIAL EVALUATION AND PROGRAM GENERATION

Partial evaluation [Consel and Danvy 1993; Danvy et al. 1996; Jones et al. 1993; Hatchfield et al. 1993; Lloyd and Shepherdson 1991; Mogensen 2000] is an example of automatic program transformation. While speedups are more limited than sometimes realizable by hand transformations based on deep problem or algorithmic knowledge, the technology is well-automated. It has already proven its utility in several different contexts:

—Scientific computing ([Berlin and Weise 1990; Glück et al. 1995], etc.);
—Extending functionality of existing languages by adding binding-time options ([Grant et al. 2000], etc.);
2.1 Equational definition of a parser generator

To get started, and to connect partial evaluation with program generation, we first exemplify our notation for program runs on an example. (Readers familiar with the field may wish to skip to Section 3.)

Parser generation is a familiar example of program generation. The construction of a parser from a grammar by a parser generator, and running the generated parser, can be described by the following two program runs:

\[
\text{parser} ::= \text{parse-gen}[\text{grammar}]
\]

\[
\text{parsetree} ::= \text{parser}[\text{inputstring}]
\]

The combined effect of the two runs can be described by a nested expression:

\[
\text{parsetree} ::= [[\text{parse-gen}][\text{grammar}]][\text{inputstring}]
\]

2.2 What goals does partial evaluation achieve?

A partial evaluator \cite{Consel93a,Jones93a,Hatch1999} is a program specializer: Suppose one is given a subject program \( p \), expecting two inputs, and the first of its input data, \( \text{in1} \) (the “static input”). The effect of specialization is to construct a new program \( p_{\text{st}} \) that, when given \( p \)'s remaining input \( \text{in2} \) (the “dynamic input”), yields the same result that \( p \) would have produced if given both inputs.

The process of partial evaluation is shown schematically in Figure 4.

\textit{Example 1.} The standard toy example for partial evaluation is the program \texttt{power}, computing \( x^n \) with code:

\[
f(n,x) = \text{if } n=0 \text{ then } 1 \text{ else if } \text{odd}(n) \text{ then } x*f(n-1,x) \text{ else } f(n/2,x)**2
\]

This example illustrates that partial evaluation in effect does an aggressive constant propagation across function calls. Specialization to static input \( n = 13 \) yields a residual program that runs several times faster than the general one above:

\[
f.13(x) = x*(((x*(x**2))**2)**2)
\]

\footnote{Notation: \( p[\text{in1},\ldots,\text{in}k] \) is a partial value: the result yielded by running program \( p \) on input values \( \text{in1},\ldots,\text{in}k \) if this computation terminates, else the \textit{undefined} value \( \perp \).}

Example 2. (Ackermann’s function) If calls are not unfolded, then specialized functions are generated in the specialized program, as seen by this example of specialization to static input $m=2$:

**Source program**

\[
\text{ack}(m,n) = \begin{cases} 
\text{if } m=0 \text{ then } n+1 & \text{else} \\
\text{if } n=0 \text{ then } \text{ack}(m-1,1) & \text{else} \\
\text{ack}(m-1,\text{ack}(m,n-1)) & 
\end{cases}
\]

**Specialized program (for $m=2$)**

\[
\text{ack}_2(n) = \begin{cases} 
\text{if } n=0 \text{ then } & \text{ack}_2(n) \\
\text{ack}_1(1) & \text{else} \\
\text{ack}_1(\text{ack}_2(n-1)) & \\
\text{ack}_0(\text{ack}_1(n-1)) & \\
\text{ack}_0(n) = n+1 
\end{cases}
\]

2.2.1 **Equational definition of a partial evaluator.** Correctness of $p_{\text{res}}$ can be described equationally as follows:

**Definition 2.2.1.** A partial evaluator $\text{spec}$ is a program such that for all programs $p$ and input data $\text{in1}$, $\text{in2}$:

\[
[[p]][\text{in1},\text{in2}] = [[[\text{spec}][p,\text{in1}]]][\text{in2}]
\]

Writing $p_{\text{res}}$ for $[[\text{spec}][p,\text{in1}]]$, the equation can be restated without nested semantic parentheses $[]$:

\[
[[p]][\text{in1},\text{in2}] = [p_{\text{res}}][\text{in2}]
\]

Program $p_{\text{res}}$ is often called the “residual program” of $p$ with respect to $\text{in1}$, as it specifies remaining computations that were not done at specialization time.

2.2.2 **Desirable properties of a partial evaluator.**

**Efficiency.** This is the main goal of partial evaluation. Run out := $[[p]][\text{in1},\text{in2}]$ is often slower than the run out := $[p_{\text{res}}][\text{in2}]$, as seen in the two examples above.

---

2 An equation $[p][\text{in1},\ldots,\text{inK}] = [q][\text{in1},\ldots,\text{inK}]$ expresses equality of partial values: if either side terminates, then the other side does too, and they yield the same value.
Said another way: It is slower to run the general program \( p \) on \( [\text{in1}, \text{in2}] \) than it is to run the specialized residual program \( p_{\text{res}} \) on \( \text{in2} \).

The reason is that, while constructing \( p_{\text{res}} \), some of \( p \)'s operations that depend only on \( \text{in1} \) have been precomputed, and some function calls have been unfolded or "inlined." These actions are never done while running \( [p_{\text{res}}][\text{in2}] \); but they will be performed every time \( [p][\text{in1}, \text{in2}] \) is run. This is especially relevant if \( p \) is run often, with \( \text{in1} \) changing less frequently than \( \text{in2} \).

Correctness. First and foremost, a partial evaluator should be correct. Today's state of the art is that most partial evaluators give correct residual programs when they terminate, but sometimes loop infinitely or sometimes give code explosion. A residual program, once constructed, will in general terminate at least as often as the program from which it was derived.

Completeness. Maximal speedup will be obtained if every computation depending only on \( \text{in1} \) is performed. For instance the specialized Ackermann program above, while faster than the original, could be improved yet more by replacing the calls \( \text{ack}_1(1) \) and \( \text{ack}_0(1) \), respectively, by constants 3 and 2.

Termination. Ideally:
—The specializer should terminate for all inputs \( [p, \text{in1}] \).
—The generated program \( p_{\text{res}} \) should terminate on \( \text{in2} \) just in case \( p \) terminates on \( [\text{in1}, \text{in2}] \).

These termination properties are easier to state than to achieve, as there is an intrinsic conflict between demands for completeness and termination of the specializer. Nonetheless, significant progress has been made in the past few years [Das 1998; Das and Reps 1996; Glenstrup 1999; Glenstrup and Jones 1996; Song and Futamura 2000]. A key is carefully to select which parts of the program should be computed at specialization time. (In the usual jargon: which parts are considered "static.")

2.2.3 A breakthrough: the generation of program generators. For the first time in the mid 1980s, a breakthrough was achieved in practice that had been foreseen by Japanese and Russian researchers early in the 1970s: the automatic generation of compilers and other program generators by self-application of a specializer. The following definitions [Futamura 1999a; Futamura 1999b] are called the Futamura projections:

Generic Futamura projections
1. \( p_{\text{res}} := [\text{spec}][p, \text{in1}] \)
2. \( p_{\text{gen}} := [\text{spec}][\text{spec}, p] \)
3. \( \text{cogen} := [\text{spec}][\text{spec}, \text{spec}] \)

Consequences:
A. \( [p][\text{in1}, \text{in2}] = [p_{\text{res}}][\text{in2}] \)
B. \( p_{\text{res}} = [p_{\text{gen}}][\text{in1}] \)
C. \( p_{\text{gen}} = [\text{cogen}][p] \)

Program \( p_{\text{gen}} \) is called \( p \)'s "generating extension." By B it is a generator of specialized versions of \( p \), that transforms static parameter \( \text{in1} \) into specialized program.
p_{ist}. Further, by C and B the program called cogen behaves as a generator of program generators.
Consequence A is immediate from Definition 2.2.1. Proof of Consequence B is by simple algebra:

\[
[p\text{-gen}][\text{in1}] = ([[\text{spec}][\text{spec}, p]] [\text{in1}]
= [\text{spec}][p, \text{in1}]
= p_{ist}
\]

By definition of p-gen
By Definition 2.2.1
By definition of p_{ist}

and consequence C is proven by similar algebraic reasoning, left to the reader.

**Efficiency gained by self-application of a partial evaluator.** Compare the two ways to specialize program p to static input \text{in1}:

I. \( p_{ist} := [[\text{spec}][p, \text{in1}] \)
II. \( p_{ist} := [p\text{-gen}][\text{in1}] \)

Way I is in practice usually several times slower than Way II. This is for exactly the same reason that \( p_{ist} \) is faster than \( p \). Way I runs \text{spec}, which is a general program that is able to specialize any program \( p \) to any \text{in1}. On the other hand, Way II runs \( p\text{-gen} \): a specialized program, only able to produce specialized versions of this particular \( p \).

By exactly the same reasoning, computing \( p\text{-gen} := [[\text{spec}][\text{spec}, p] \) is often several times slower than using the compiler generator \( p\text{-gen} := [\text{cogen}][p] \).

Writing cogen instead of spec. In a sense, any program generator is a "generating extension," but without an explicitly given general source program \( p \). To see this, consider the two runs of the parser generator example:

\[
\begin{align*}
\text{parser} & := [[\text{parse-gen}][\text{grammar}] \\
\text{parsetree} & := [[\text{parser}][\text{input_string}] \\
\text{parsetree} & = \text{[universal-parser][grammar, input_string]} \\
\end{align*}
\]

Here in principle a universal parser (e.g., Earley's parser) satisfying:

\[
\text{parsetree} = \text{[universal-parser][grammar, input_string]}
\]

could have been used to obtain \( \text{parse-gen} \) as a generating extension:

\[
\text{parse-gen} := [\text{cogen}][\text{universal-parser}]
\]

Further, modern specializers such as C-mix [Glenstrup et al. 1999], Tempo [Consol and Noël 1996], PGG [Thiemann 1999] and SML-mix [Birkedal and Weilnder 1994] are cogen programs written directly, rather than built using self-application of spec as described above and in the literature [Jones et al. 1993]. (Descriptions of the idea can be found in [Birkedal and Weilnder 1994] [Holst and Launchbury 1991] [Thiemann 1997].) Although not built by self-application, the net effect is the same: programs can be specialized; and a program may be converted into a generating extension with respect to its static parameter values.

2.2.4 **Front-end compilation: an important case of the Futamura projections.** Suppose that we now have two languages: the specializer's input-output language
L, and another language S that is to be implemented. Let \([\_]^S\) be the “semantic function” that assigns meanings to S-programs.

**Definition 2.2.2.** Program interp is an interpreter for language S written in language L if for any S-program source and input in,

\[ [\text{source}]^S[\text{in}] = [\text{interp}][\text{source, in}] \]

(See Figure 2 in Section 2.2.3 for an example interpreter.) We now apply the Futamura projections with some renaming. Replace program p by interp, static input in1 by S-program source, dynamic input in2 by in, and p-gen by compiler.

**Compilation by the Futamura projections**

1. target := [spec][interp, source]
2. compiler := [spec][spec, interp]
3. cogen := [spec][spec, spec]

After this renaming, the “Consequences” of Section 2.2.3 become:

A. \([\text{interp}][\text{source, in}] = [\text{target}][\text{in}]\)
B. target = [compiler][source]
C. compiler = [cogen][interp]

Program target deserves its name, since it is an L-program with the same input-output behavior as S-program source:

\[ [\text{source}]^S[\text{in}] = [\text{interp}][\text{source, in}] = [\text{target}][\text{in}] \]

Further, by the other consequences program compiler = interp-gen transforms source into target and so really is a compiler from S to L; and cogen is a compiler generator that transforms interpreters into compilers.

The compilation application of specialization imposes some natural demands on the quality of the specialization:

— The compiler interp-gen must terminate for all source program inputs.
— The target programs should be free of all source code from program source.

2.2.5 Example of compiling by specializing an interpreter: Consider the simple interpreter interp given by the pseudocode in Figure 2("). An interpreted source program (to compute the factorial function \(n!\)) might be:

\[ \text{pg} = (\text{if } (\text{n x}) (\text{if } (= (\text{n}, 0) \text{ then } 1 \text{ else } (* (\text{x}, \text{call } (\text{f}(-(\text{n}, 1), \text{x})))))) \]

Let target = [spec][interp, pg] be the result of specializing interp to static source program pg. Any reasonable compiler should “specialize away” all source code. In particular, all computations involving syntactic parameters pg, e and ns should be done at specialization time (considered as ‘static’).\(^3\)

\(^3\)The interpreter is written as a first-order functional program, using Lisp “S-expressions” as data values. The current binding of names to values is represented by two lists: ns for names, and parallel list vs for their values. For instance computation of \([\text{interp}][\text{pg}, [2, 3]]\) would use initial environment ns = \([\text{n x}]\) and vs = \([2, 3]\).

Operations are car, cdr corresponding to ML’s hd, tl, with abbreviations such as \(\text{car}(x)\) for \(\text{car}(\text{cdr}(x))\).
run\((\text{prog},\text{d})\) = \{ \text{eval(\text{lkbody('main',\text{prog}),\text{lkparam('main',\text{prog}), d, prog}})} \}

eval\((\text{e},\text{ns,vs,pg})\) = \text{case e of}
\begin{align*}
\text{c} & : \text{valueof(c)} \\
\text{x} & : \text{lkvar(x, ns, vs)} \\
\text{baseln(e1,\ldots,e_n)} & : \text{apply(baseln, eval(e1, ns, vs, pg), \ldots, eval(e_n, ns, vs, pg))} \\
\text{let x = e1 in e2} & : [x]\text{eval(e2, ns, vs, pg),} \\
\text{cons(x, y)} & : \text{eval(x, ns, vs, pg),} \\
\text{cons(x, eval(e1, ns, vs, pg), vs),} \\
\text{pg)} \\
\text{if e1 then e2 else e3:} & \text{if e1 then eval(e1, ns, vs, pg)} \\
\text{then eval(e2, ns, vs, pg)} \\
\text{else eval(e3, ns, vs, pg)} \\
call\((\text{e1,\ldots,e_n}) & : [\text{eval(\text{lkbody(f,pg}),}} \\
& \text{\text{lkparam(f,pg),}} \\
& \text{\text{list[0]eval(e1, ns, vs, pg), \ldots,}} \\
& \text{\text{eval(e_n, ns, vs, pg))},}} \\
& \text{pg) } \\
\text{lkbody(f,pg) = if caar(pg)=f then cadar(pg) else lkbody(f, cdr(pg))}} \\
\text{lkparam(f,pg) = if caar(pg)=f then cadar(pg) else lkparam(f, cdr(pg))}} \\
\text{lkvar(x,ns,vs) = if car(ns)=x then cdr(vs) else lkvar(x, cdr(ns), cdr(vs))}} \\
\end{align*}

Fig. 2. interpreter for a small functional language. Parameter e is an expression to be evaluated; ns is a list of parameter names, vs is a parallel list of values, and pg is a program (for an example, see Section 2.2.3) The \text{lkparam and lkbody functions find a function's parameter list and its body. lkvar looks up the name of a parameter in ns, and returns the corresponding element of vs.}

For instance, when given the source program above, we might obtain a specialized program like this:
\[
\text{eval}_f(\text{vs}) = \\
\begin{align*}
\text{if apply('=', car(vs), 0) then 1 else} \\
\text{apply('*, cadr(vs),} \\
& \text{eval}_f(\text{list\{apply('=', car(vs), 1), cadr(vs)\}}))
\end{align*}
\]

Clearly, running \text{eval}_f(d) is several times faster than running \text{run(pg,d)}.

2.3 How does partial evaluation achieve its goals?

Partial evaluation is analogous to memoization, but not the same. Instead of saving a complete \textit{value} for later retrieval, a partial evaluator generates \textit{specialized code}.

\footnote{Still better code can be generated! Since list \text{vs} always has length 2, it could be split into two components v1 and v2. Further generic \textit{apply(op,\ldots,y)} can be replaced by specialized \textit{"op(\ldots,y."}. These give a program essentially identical to the interpreter input:
\[
\text{eval}_f(\text{v1,v2) = if = (v1,0) then 1 else v2,eval}_f(-(v1,1), v2))
\]

This is as good as can reasonably be expected, cf. the discussion of “optimal” specialization in Jones et al., 1993; Tabua et al., 2004.
(possibly containing loops) that will be executed at a later stage in time.

The specialization process is easy to understand provided the residual program
contains no loops, e.g., the “power” function seen earlier can be specialized by computing values statically when possible, and generating residual code for all
remaining operations. But how to proceed if residual program loops are needed,
e.g., as in the “Ackermann” example, or when specializing an interpreter to compile
a source program that contains repetitive constructs? One answer is program-point
specialization.

2.3.1 Program-point specialization. Most if not all partial evaluators employ
some form of the principle: A control point in the specializer’s output program
corresponds to a pair (pp, us): a source program control point pp, plus some knowl-
dge (“static data”) us about of the source program’s runtime state. An example
is shown for Ackermann’s function in Figure 3 (program points are labeled by boxed
numbers.) Residual functions ack_2, ack_1, ack_0 correspond to program point 0
(entry to function ack) and known values m = 2, 1, 0, respectively.

2.3.2 Sketch of a generic expression reduction algorithm. To make the issues
clearer and more concrete, let exp be an expression and let us be the known infor-
mation about program p’s run-time state.

The“reduced” or residual expression $\text{exp}^{\text{resid}}$ can be computed roughly as follows:

Expression reduction algorithm Reduce(exp, us):

1. Reduce any subexpressions $e_1, \ldots, e_n$ of $\text{exp}$ to $e_1^{\text{resid}}, \ldots, e_n^{\text{resid}}$.

\footnote{This knowledge can take various forms, and is often a term with free variables. For simplicity we will assume in the following that at specialization time every parameter is either fully static (totally known) or fully dynamic (totally unknown), i.e., that there is no partially known data. Some partial evaluators are more liberal, for example, allowing lists of statically known length with dynamic elements. This is especially important in partial evaluation of Prolog programs or for supercompilation [Glick and Sorensen 1996; Louschel and Bruynooghe 2002; Sorensen and
Glicht 1995; Turpin 1990].}
(2) If \( \text{exp} = \text{"basefn}(e_1, \ldots, e_n)" \) and some \( e_i^{\text{resid}} \) is not fully known, then
\[ \text{exp}^{\text{resid}} = \text{the residual expression } \text{"basefn}(e_1^{\text{resid}}, \ldots, e_n^{\text{resid}}) \], else
\[ \text{exp}^{\text{resid}} = \text{the value } \text{basefn}(e_1, \ldots, e_n^{\text{resid}}). \]

(3) If \( \text{exp} = \text{"if } e_0 \text{ then } e_1 \text{ else } e_2 \" \) and \( e_0^{\text{resid}} \) is not fully known, then
\[ \text{exp}^{\text{resid}} = \text{the residual expression } \text{"if } e_0^{\text{resid}} \text{ then } e_1^{\text{resid}} \text{ else } e_2^{\text{resid}} \], else
\[ \text{exp}^{\text{resid}} = e_0^{\text{resid}} \text{ in case } e_0^{\text{resid}} = \text{"True"}, \text{ else } \text{exp}^{\text{resid}} = e_2^{\text{resid}}. \]

(4) A function call \( \text{exp} = \text{"f}(e_1, \ldots, e_n)\" \) can either be
- Residualized: \( \text{exp}^{\text{resid}} = \text{f}(e_1^{\text{resid}}, \ldots, e_n^{\text{resid}}) \) with some known \( e_i \) omitted,[9]
- Or unfolded: \( \text{exp}^{\text{resid}} = \text{Reduce(definition of } f, \text{ vs}') \)
  where \text{vs}' is the static knowledge about \( e_1^{\text{resid}} \ldots e_n^{\text{resid}} \).

This algorithm computes expression values depending only on static data, reduces static "if" constructs to their "then" or "else" branches, and either unfolds or residualizes function calls. The latter enables the creation of loops (recursion) in the specialized program. Any expression computation or "if"-branching that depends on dynamic data is postponed by generating code to do the computation in the specialized program.

Naturally, an expression may be reached several times by the specializer (it may be in a recursive function). If this program point and the current values of the source program, \((\text{pp}, \text{vs})\), have been seen before, one of two things can happen: If \( \text{pp} \) has been identified as a specialization point, the specializer generates a call in the specialized program to the code generated previously for \((\text{pp}, \text{vs})\). Otherwise, the call is unfolded and specialization continues as usual.

This sketch leaves several choices unspecified, in particular:

—Whether or not to unfold a function call
—Which among the known function arguments are to be removed (if any)

2.3.3 Causes of nontermination during specialization. First, we show an example of nontermination during specialization. A partial evaluator should not indiscriminately compute computable static values and unfold function calls, as this can cause specialization to loop infinitely even when normal evaluation would not do so. For example, the following program computing 2x in "base 1" terminates for any \( x \):

\[
\begin{align*}
\text{double(x)} &= \text{dblplus(x,0)} \\
\text{dblplus(u,v)} &= \text{if } u < 0 \text{ then } v \text{ else } \text{dblplus(u-1,v+2)}
\end{align*}
\]

Now suppose \( x \) is a dynamic (unknown) program input. A naïve specializer might "reason" that parameter \( v \) first has value 0, a constant known at specialization time. Further, if at any stage the specializer knows one value \( v \) of \( v \), then it can compute its next value, \( v + 2 \). Alas, repeatedly unfolding calls to \text{dblplus} assigns to \( v \) the values 0, 2, 4, 6, . . . causing an infinite loop at specialization time.

The way to avoid this problem is to not unfold the second \text{dblplus} call. The effect is to generalize \( v \), i.e., to make it dynamic.

---

[9] If a function call is residualized, a definition of a specialized function must also be constructed by applying \text{Reduce} to the function's definition.
Definition 2.3.1. A parameter \( x \) will be called potentially static if dynamic program inputs are not needed to compute its value.

Three effects are the main causes of nontermination in partial evaluation:

1. A loop controlled by a dynamic conditional can involve a potentially static parameter that takes on infinitely many values, generating an infinite set of specialized program control points \( \{(pp, v_1), (pp, v_2), \ldots\} \). Parameter \( v \) of function \( \text{db1plus} \) illustrates this behavior.
2. A too liberal policy for unfolding of function calls can cause an attempt to generate an infinitely large specialized program.
3. As both branches of dynamic conditionals are (partially) evaluated, partial evaluation is over-stric in the sense that it may evaluate more expressions than normal evaluation would, and thus risk nontermination not present in the source program being specialized.

If there is danger of specializing a function with respect to infinitely many static values, then some of the parameters in question should be generalized, i.e., made dynamic. Instead of specializing the function with respect to all potentially static values, some will then become parameters in the specialized program, to be computed at run-time.

We will show how this can be done automatically, before specialization begins (of automation degree in the list of Section 2.4). A companion goal is to unfold function calls “just enough but not too much.”

2.3.4 Online and offline specialization. \( \) Partial evaluators fall in two categories, on-line and off-line, according to the time at which it is decided whether parameters should be generalized or calls should be unfolded (cf. Step 4 of the \textit{Reduce} algorithm).

An online specializer generalizes during specialization. Usually this involves, at each call to a function \( f \), comparing the newly-computed static arguments with the values of all parameters seen in earlier calls to \( f \), in order to detect potentially infinite value sequences.\cite{berlin-weise:1990, gallagher:1993, leuschel:1998, leuschel:2002, sorensen:1995, turchin:1979} An online specializer works in two stages. Stage 1, called a binding-time analysis (BTA for short) yields an annotated program in which:

- each parameter is marked as either “static” or “dynamic,”
- each expression is marked as “reduce” or “specialize,” and
- each call is marked as “unfold” or “residualize.”

Both kinds of specialization have their merits. Online specialization sometimes does more reduction: For example, in the specialization of Ackermann's function in Figure 4, when the call at site 3 is unfolded, an online specializer will realize that the value of \( n \) is known and compute the function call. In contrast, the binding-time analysis of offline specialization must classify \( n \) as dynamic at call site 4, since its value is not known at call site 4.

Although an online specializer can sometimes exploit static data better, this extra precision comes at a cost. A major problem is how to determine online when to stop unfolding function calls. Comparison of us with previously seen values can result in an extremely slow specialization phase, and the specialized program may be inefficient if specialization is stopped too soon.

An offline specializer is often faster since it needs to do no decision-making online: it only has to obey the annotations. Further, full self-application, as in the Futamura projections, has to date only been achieved by using offline methods.

2.4 Multi-level programming languages

Many informal algorithm optimizations work by changing the times at which computations are done, e.g., by moving computations out of loops; by caching values in memory or in files for future reference; or by generating code implicitly containing partial results of earlier computations. Such a change to an algorithm is sometimes called a staging transformation, or a binding-time shift. The field of domain-specific languages\footnote{Some partial evaluators allow more static computation than in in the present paper by using polyvariant BTA, in which the binding-time analysis can generate a finite set of different combinations of static and dynamic parameters [Christensen et al. 2000; Consel 1993].} employs similar strategies to improve efficiency. Partial evaluation automates this widely-used principle to gain speedup.

A BTA-annotated program can be thought of as a program in a two-level language in which statically annotated parts are executed, while the syntactically similar dynamic parts are in effect templates for generation of code to be executed at a later time. This line of thinking has been developed much further, e.g., by Grant et al. [2000] and, for typed languages, in Sheard's Meta-ML work [Moggi et al. 1999; Sheard 1999; Taha and Sheard 2000], and later in Taha's thesis and subsequent papers [Taha 1999b; Taha 1999a; Taha et al. 2001]. Goals of the work include efficiency improvement by staging computations; understanding how multi-level languages may be designed and implemented; resolution of tricky semantic issues, in particular questions of renaming; and formal proofs to guarantee that multi-level type safety can be achieved. A recent paper applies these ideas to ensure type-safe use of macros [Ganz et al. 2001].

Termination remains, however, a problem to be solved one case at a time by the programmer. Conceivably the ideas of this paper could contribute to a future strongly-terminating multi-level language.

Remark on language evolution. Figure 1 assumes that \( p_{143} \) is an explicit, printable program. A program in a multi-level language such as Meta-ML can construct program fragments as data values and then run them, but it does not produce stand-alone, separately executable programs.
Meta-ML is an interesting example of internalization of a concept about programming languages into a programming language construct. Analogous developments have happened before: continuations were developed to explain semantics of the goto and other control structures, but were quickly incorporated into new functional languages. Multi-level languages perhaps derive similarly from internalizing the fact that one language's semantics can be defined within another language, a concept also seen in Smith, Wand, Danvy and Asai's "reflective tower" languages 3-Lisp, Brown, Blonde and Black, G. Rivieres and Smith 1984, Friedman and Wand 1984; Wand and Friedman 1988; Danvy and Malmkjær 1988; Bawden 1988; Jefferson and Friedman 1996.

2.5 Challenging problems

2.5.1 On the state of the art in partial evaluation. Partial evaluation has been most successful on simple "pure" languages such as Scheme [Bondorf 1991], Bondorf and Jørgensen 1993; Consel 1993], Lawall and Thiemann 1997] and Prolog [De Schreye et al. 1999], and there has been some success on C: the C-mix [Glenstrup et al. 1999] and Tempo systems [Consel and Noel 1996]. Further, Schulz has succeeded in doing Java specialization by translating Java to C, using the Tempo system, and then translating back [Schulz 2001].

There have been a number of practically useful applications of partial evaluation, many exploiting its ability to build program generators [Glick et al. 1995], Jones 1996; McNamara et al. 2001; Lawall and Thiemann 1997; Sperber and Thiemann 2000].

Partial evaluation also has some weaknesses. One is that speedups are at most linear in the subject program's runtime (although the size of the constant coefficient can be a function of the static input data.) Further, its use can be delicate: Obtaining good speedups requires a close knowledge of the program to be specialized, and some "binding-time improvements" may be needed to get expected speedups. (These are hand work, of automation degree [in the list of Section 1.3].) Another weakness is that the results of specialization can be hard to predict: While speedup is common, slowdown is also possible, as is the possibility of code explosion or infinite loops at specialization time.

Little success has been achieved to date on partial evaluation of the language C++, largely due to its complex, unclear semantics; or on Java, C#, and other languages with objects, polymorphism, modules and concurrency.

One reason for the limited success in these languages is that partial evaluation requires precomputing as much as is possible, based on partial knowledge of a program's input data. To do this requires anticipating, at specialization time, the space of all possible run-time states. Such analysis can be done by abstract interpretation [Consol and Consol 1977; Jones and Nielson 1994] for simple functional or logic programming languages, but becomes much more difficult for more complex or more dynamic program semantics, as both factors hinder the specialization-time prediction of run-time actions.

Languages such as C++, Java and C# seem at the moment to be too complex to be sufficiently precisely analyzed, and to allow reliable assurances that program semantics is preserved under specialization.
2.5.2. How to make specialization terminate. Reliable termination properties are essential for highly automatic program manipulation—and are not perfect in existing partial evaluation systems. In fact, few papers have appeared on the subject, exceptions being the promising but unimplemented [Song and Futamura 2000] and works by Das and Glenstrup [Das 1998; Das and Reps 1996; Glenstrup 1999; Glenstrup and Jones 1996]. Although the generation of program generators is a significant accomplishment with promise for wider applications, program generator generation places high demands on predictability in the behavior of specialized output programs, and on the specialization process itself.

Termination of specialization can always be achieved; an extreme way is to make everything dynamic. This is useless, though, because no computations at all occur at specialization time and the specialized program is only a copy of the source program.

Our goal is to specialize in a way that maximizes the number of static computations, but nonetheless guarantees termination. As a “stepping stone” in order to achieve the two-level termination required for partial evaluation, we first investigate a novel automatic approach to ordinary termination analysis.

3. PROGRAM TERMINATION BY “SIZE-CHANGE ANALYSIS”

Our ultimate goal is to ensure, given program \( p \), that program specialization: \( p_{\text{int}} = \tau_{\text{spec}}[p, \text{in1}] \) will terminate for all inputs \( \text{in1} \). Before explaining our solution to this subtle problem, we describe an automated solution to a simpler problem: how to decide whether a (one-stage) program terminates on all inputs. The termination problem is interesting in itself, of considerable practical interest, and has been studied by several communities: logic programming [Lindenstrauss et al. 1997], term rewriting [Arts and Giesl 1997], functional programming [Abel and Altenkirch 1999; Lee et al. 2001; Xi 2002] and partial evaluation [Das 1998; Das and Reps 1996; Glenstrup 1999; Glenstrup and Jones 1996; Song and Futamura 2000].

A guarantee of termination is hard to achieve in practice, and undecidable in general (it is the notorious uniform halting problem). Still, dependable positive answers are essential in practice to ensure system liveness properties: that a system will never “hang” in an infinite loop, but continue to offer necessary services and make progress towards its goals. To this end, we have recently had some success in using size-change analysis to detect termination [Lee et al. 2001].

3.1 The size-change termination principle

Size-change analysis is based only on local information about parameter values. The starting point is a “size-change graph,” \( G_c \), one for each call \( c : f \rightarrow g \) from function \( f \) to function \( g \) in the program. Graph \( G_c \) describes parameter value changes when call \( c \) is made (only equalities and decreases). The graphs are derivable from program syntax, using elementary properties of base functions (plus a size analysis to describe the results of nested function calls, see [Chin and Khoo 2002; Hughes et al. 1996; Jones et al. 1993]).

In the following, we shall consider programs written in a first-order functional
language with well-founded data\(^4\) and we say that a call sequence \(cs = c_1c_2 \ldots\) is \textit{valid} for a program if it follows the program’s control flow. The key to our termination analyses is the following principle:

A program terminates (on any input to any function) if every valid infinite call sequence would, if executed, cause an infinite decrease in some parameter values.

\textit{Example of size-change termination analysis.} Consider a program on natural numbers that uses mutual recursion to compute \(2^x \cdot y\).

\[
f(x, y) = \text{if } x = 0 \text{ then } y \text{ else } g(x, y, 0) \\
g(u, v, w) = \text{if } v > 0 \text{ then } g(u, v-1, w+2) \text{ else } f(u-1, w)
\]

Following are the three size-change graphs for this program, along with its call graph and a description of its valid infinite call sequences. There is one size-change graph \(G_c\) for each call \(c\), describing both the data flow and the parameter size changes that occur if that call is taken. To keep the analysis simple, we approximate the size changes by either \(\uparrow\) (the change does not increase the value) or \(\downarrow\) (the change decreases the value); normally we omit the \(\uparrow\) labels from graphs for readability. The valid infinite call sequences can be seen from the call graph, and are indicated by \(\omega\)-regular expressions\(^6\).

\[
\text{Size-change graphs} \\
G_1 \hspace{1cm} G_2 \hspace{1cm} G_3
\]

\[
\text{Valid infinite call sequences} \\
(12^3)^\omega + (12^3)^*12^\omega
\]

\textit{An informal argument for termination.} Examination of the size-change graphs reveals that a call sequence ending in \(12^\omega\) causes parameter \(v\) to decrease infinitely, but is impossible by the assumption that data values are well-founded. Similarly, a call sequence in \((12^3)^\omega\) causes parameters \(x\) and \(u\) to decrease infinitely. The natural numbers are well-formed, so both are impossible. Consequently no valid infinite call sequence is possible, so the program terminates.

\(^4\)I.e., no infinitely decreasing value sequences are possible. With the aid of other analyses this assumption may be relaxed so as to cover, for example, the integers.

\(^6\)\(\omega\) indicates any finite number of repetitions, and \(\omega\) indicates an infinite number of repetitions.

3.2 A termination algorithm

It turns out that the set of valid infinite call sequences that cause infinite descent in some value is finitely describable\cite{Lee1}. Perhaps surprisingly, the infinite descent property is decidable, e.g., by automata-theoretic algorithms. We sketch an algorithm operating directly on the size-change graphs without the passage to automata.

Two size-change graphs \( G : f \rightarrow g \) and \( G' : g \rightarrow h \) may be composed in an obvious way to yield a size-change graph \( G; G' : f \rightarrow h \). Their total effect can be expressed in a single size-change graph, like \( G_{13} = G_1; G_3 \), shown below. These compositions are used in the central theorem of Lee et al.\cite{Lee1}:

**Theorem 3.2.1.** Let the closure \( S \) of the size-change graphs for program \( p \) be the smallest graph set containing the given size-change graphs, such that \( G; G' \in S \) whenever \( S \) contains both \( G : f \rightarrow g \) and \( G' : g \rightarrow h \). Then \( p \) is size-change terminating if and only if every idempotent \( G \in S \) (i.e., every graph satisfying \( G = G; G \)) has an in situ descent \( z \rightarrow z \).

The closure set for the example program is:

\[
S = \{ G_1, G_2, G_3, G_{12}, G_{13}, G_{131}, G_{23}, G_{231}, G_{31}, G_{312} \}
\]

This theorem leads to a straightforward algorithm. The idempotent graphs in \( S \) are \( G_2 \) (above) as well as \( G_{13} \) and \( G_{231} \) (below). Each of them has an in situ decreasing parameter, so no infinite computations are possible.

3.3 Assessment

Compared to other results in the literature, termination analysis based on the size-change principle is surprisingly simple and general: lexicographical orders, indirect function calls and permuted arguments (descent that is not in-situ) are all handled automatically and without special treatment, with no need for manually supplied argument orders, or theorem-proving methods not certain to terminate at analysis time. It has recently been proven Ben-Amram\cite{Ben-Aram2} that the functions computable by size-change terminating are exactly Péter’s “multiple recursive” functions [Péter\cite{Péter1976}]. This is an enormous class, so the expressive power of size-change terminating programs is quite high.

*Converging insights.* This termination analysis technique has a history of independent rediscovery. We first discovered the principle while trying to communicate our earlier, rather complex, binding-time analysis algorithms to ensure termination of specialization\cite{Glenstrup1999,Glenstrup1999a}. The size-change termination principle arose while trying to explain our methods simply, by starting

---

\(^{10}\) It is an \( \omega \)-regular set, representable by a Büchi automaton.

with one-stage computations as an easier special case \cite{Lee:2001}. To our surprise, the necessary reformulations led to BTA algorithms that were stronger as well as easier to explain.

Independently, Lindenstrauss and Sagiv had devised some more complex graphs to analyze termination of logic programs \cite{Lindenstrauss:1997}, based on the same mathematical properties as our method. A third discovery: the Sistla-Vardi-Wolper algorithm for determinization of Büchi automata \cite{PrasadSistla:1987} resembles our closure construction. This is no coincidence, as the infinite descent condition is quite close to the condition for acceptance of an infinite string by a Büchi automaton.

**Termination analysis in practice.** Given the importance of the subject, it seems that surprisingly few termination analyses have been implemented. In logic programming, the Termilog analyzer \cite{Lindenstrauss:1997} can be run from a web page; and the Mercury termination analysis \cite{Speirs:1997} has been applied to all the programs comprising the Mercury compiler. In functional programming, analyses by \cite{Abel:1999} and \cite{Lee:2001} have both been implemented as part of the AGDA proof assistant \cite{Coquand:2001}. Further, \cite{Ki:2002} uses dependent types with user-supplied annotations to verify termination, and \cite{Grobauer:2001} refines this approach to verify run-time bounds. A recent paper on termination analysis of imperative programs is written by \cite{Colon:2002}.

### 3.4 Quatermination

The following closely related concept will turn out to be central for ensuring that partial evaluation terminates. A quaterminating program is one that enters only finitely many different states during any one computation. Of course, any terminating program is also quaterminating.

**Definition 3.4.1.** Program $p$ is quaterminating iff for any input vector $\overline{m}$, the following is a finite set:

\[ \text{Reach}(\overline{m}) = \{ (\overline{f}, \overline{v}) \mid \text{Computation of } \overline{\text{p}[\overline{m}]} \text{ calls } \overline{f} \text{ with argument } \overline{v} \} \]

This can be re-expressed in terms of properties of individual function parameters:

**Definition 3.4.2.** Assume program $p$ contains the definition \( f(x_1, \ldots, x_n) = \) expression. The variation of parameter $x_i$ for program input $\overline{m}$ is the set:

\[ \text{Var}(x_i, \overline{m}) = \{ v_i \mid (\overline{f}, v_1 \ldots v_n) \in \text{Reach}(\overline{m}) \text{ for some inputs } \overline{m} \} \]

We say $x_i$ is of bounded variation (written BV, for short) if for every input $\overline{m}$ the set $\text{Var}(x_i, \overline{m})$ is finite.

**Lemma 3.4.3.** Program $p$ is quaterminating if and only if all its parameters are of bounded variation.

A simple example: program \texttt{double} of Section 2.3.3 is terminating, and thus also quaterminating. The variations of its parameters:

\[
\begin{align*}
\text{Var}(x, x) & = \{ x \} \\
\text{Var}(u, x) & = \{ x, x - 1, \ldots, 1, 0 \} \\
\text{Var}(v, x) & = \{ 0, 2, \ldots, 2x \}
\end{align*}
\]
4. GUARANTEEING TERMINATION OF PROGRAM GENERATION

We now show how to extend the size-change principle to an analysis to guarantee termination of specialization in partial evaluation. The results described here are significantly better than those of Chapter 14 in Jones et al. 1993, and Glenstrup 1999; Glenstrup and Jones 1996. Although the line of reasoning is similar, the following results are stronger and more precise, further, a prototype implementation exists.

4.1 Online specialization with guaranteed termination

Most online specializers record the values of the function parameters seen during specialization, so that current static values vs can be compared with earlier ones in order to detect potentially infinite value sequences. A rather simple strategy (residualize whenever any function argument value increases) is sufficient to give good results on the Ackermann example seen earlier.

More liberal conditions that guarantee termination of specialization will yield more efficient residual programs. The most liberal conditions known to the authors employ variants of the Kruskal tree condition called “homeomorphic embedding” Sørensen and Glück 1993. This test, carried out during specialization, seems expensive but strong. It is evaluated on a variety of test examples in the literature Lengauer 1995.

4.2 Online specialization with call-free residual programs

The termination-detecting techniques of Section 4.3 can easily be extended to find a sufficient precondition for online specialization termination to yield call-free residual programs. The idea is to modify the size-change termination principle as follows (recall Section 2.3, Definition 2.3.1):

Suppose every valid infinite call sequence causes an infinite descent in some potentially static parameter. Then online program specialization will terminate on any static input, to yield a call-free residual program.

A program passing this test will have no infinite specialization-time call sequences. This means that an online specializer may proceed blindly, computing every potentially static value and unfolding all function calls.

This condition can be tested by a slight extension of the closure algorithm of Section 4.3

—Before specialization, identify the set $PS$ of potentially static parameters.
—Construct the closure $S$ as in Section 4.3
—Decide this question: Does every idempotent graph $G \in S$ have an in situ decreasing parameter in $PS$?

Strengths:

(1) No comparisons or homeomorphic embedding tests are required, so specialization is quite fast.

(2) The condition succeeds on many programs, e.g.,
— the “power” example of Section 2.2 specialized to static input n, or
— Ackermann’s function specialized to static m and n.

(3) If a size-change terminating program has no dynamic inputs, the test above will succeed and residual programs will have the form \( f(_{n}) = \text{constant} \).

(4) Further, any program passing this test is free of “static loops,” a notorious cause of nonterminating partial evaluation.

Weakness. The method fails, however, for the Ackermann example with static \( m \) and dynamic \( n \), or for interpreter specialization with static program argument \( pg \). The problem is that specialized versions of such programs must contain loops.

4.3 Offline specialization of an interpreter

As mentioned in Section 2.2.1, the property that source syntax is “specialized away” is vital for compiling efficient target programs, and when performing self-application of the specialization to generate compilers. Our main goal is to achieve a high degree of specialization (i.e., a fast specialized program) and at the same time a guarantee that the specialization phase terminates.

Consider specializing the simple interpreter \( \text{interp} \) of Figure 2 (Section 2.2.1) to static source program \( pg \) and dynamic program input \( d \). One would hope and expect all source code to be specialized away—in particular, syntactic parameters \( pg, e \) and \( ns \) should be classified as “static” and so not appear in target programs.

In Figure 2 parameter \( vs \) is dependent on dynamic program input \( d \), and so must appear in the specialized programs. Parameter \( pg \) always equals static input \( prog \) (it is only copied in all calls), so any specializer should make it static.

Parameter \( e \) decreases at every call site except \( \text{[1]} \) where it is reset (always to a subterm of \( pg \)). After initialization or this reset, parameter \( ns \) is only copied, except at call site \( \text{[2]} \) where it is increased.

A typical online specializer might see at call site \( \text{[3]} \) that \( \text{eval} \)'s first argument \( e \) has a value larger than any previously encountered, and thus would consider it dynamic. By the same reasoning, argument \( ns \) would be considered dynamic at call site \( \text{[4]} \) due to the evident risk of unboundedness. Alas, such classifications will yield unacceptably poor target programs.

However the binding-time analysis of an offline partial evaluator considers the interpreter program as a whole, and can detect that \( \text{eval} \)'s first argument can only range over subterms of the function bodies in the interpreted program \( pg \). This means that parameter \( e \) can be considered as “static” without risking nontermination, and can thus be specialized away. Further, parameter \( ns \) will always be a part of the interpreter's program input \( pg \). Offline specialization can recognize these facts, and so ensure that no source code from \( pg \) appears in any target program produced by specializing this interpreter.

Conclusion: control of the specializer's termination is easier offline than “on the fly.” The effect just described is not easily achieved by online methods.

Parameters that are reset to bounded values. We now describe a more subtle automatic “boundedness” analysis that reveals that the set of values \( ns \) ranges over during specialization is also finite.\(^{11}\) First, some terminology.

Remark: this is a delicate property, holding only because this \( \text{interp} \) implements “static name binding.” Changing the \( \text{call} \) code as follows to implement dynamic name binding would make \( ns \) necessarily dynamic during specialization:

---

4.4 Bounded static variation

A necessary condition for termination of offline specialization is that all of the program’s static parameters are of bounded variation. We define this more precisely:

Definition 4.4.1. Assume program p contains the definition $f(x_1, \ldots, x_n) =$ expression. Parameter $x_i$ is of bounded static variation (BSV for short) if for all static inputs $\overline{m}$, the following set is finite:

$$\text{StatVar}(x_i, \overline{m}) = \left\{ v_i \mid (f, v_1 \ldots v_n) \in \text{Reach}(\overline{m}) \text{ for some inputs } \overline{m} \text{ with } \overline{m} = \text{staticpart}(\overline{m}) \right\}$$

Two illustrative examples both concern the program double of Section 2.2. Program double is terminating; and parameter $u$ is of BSV, while $v$ is not.

$$\text{double}(x) = \begin{cases} 1 & \text{dblplus}(x, 0) \\ \text{dblplus}(u, v) \text{ if } u \leq 0 \text{ then } v \text{ else } \text{dblplus}(u-1, v+2) \end{cases}$$

Case 1. Input $x$ is static, and

$$\text{StatVar}(u, x) = \{x, x-1, \ldots, 1, 0\}$$

$$\text{StatVar}(v, x) = \{0, 2, \ldots, 2x\}$$

Both are finite for any static input $x$. The BTA can annotate both $u$ and $v$ as static because $\text{dblplus}$ will only be called with finitely many value pairs $(u, v) = (x, 0)$, $(x-1, 2), \ldots, (0, 2x)$, where $x$ is the initial value of $x$.

Case 2. Input $x$ is dynamic, and

$$\text{StatVar}(u, \varepsilon) = \{0, 1, 2, \ldots\}$$

$$\text{StatVar}(v, \varepsilon) = \{0, 2, 4, \ldots\}$$

(Here $\varepsilon$ is the empty list of static program inputs.) Here $u$ must be dynamic since it depends on dynamic input $x$. Further, even though $v$ is computed without use of dynamic inputs, the BTA must not annotate $v$ as static: If it did so, then $\text{dblplus}$ would be specialized infinitely, to: $v = 0, v = 2, v = 4, \ldots$

4.5 ‘Must-decrease’ and ‘may-increase’ properties

Detecting violations of the BSV condition requires, in addition to the must-decrease parameter size properties on which size-change termination is based, may-increase properties as well. Abstract interpretation or constraint solving analyses may be used to detect both modalities of size-change behavior, and can be found in the literature [Chin and Kho 2002; Hughes et al. 1996]. We develop analyses for the current context in Section 5 in the style of Jones et al. [1993] Section 14.3.

A simple extension of the size-change graph formalism uses two-layered size-change graphs $G = (G^2, G^3)$ where (as before) $G^3$ approximates “must-decrease” properties on which the size-change approach is based, and $G^2$ safely approximates “may-increase” size relations by arcs $x \rightarrow y$. An example: the double program seen before has two-layered size-change graphs:

```cpp
\text{call f(e_1, \ldots, e_n)}: \begin{cases} 1 \text{ eval(1body(f,pg), append(lkparens(f,pg),ms),\ldots}) \end{cases}
```

4.6 Constraints on binding-time analysis

The purpose of binding-time analysis is safely to annotate a program. The central task is to find a so-called division \( \beta : \text{ParameterNames} \rightarrow \{S, D, ?\} \) that classifies every function parameter as “static,” “dynamic,” or “as yet undecided.” The desired division should have no ?-values and be “as static as possible” while ensuring that specialization will terminate in all cases. To this end define \( \beta \supseteq \beta' \) to hold iff \( \beta'(x) \neq ? \) implies \( \beta(x) = \beta'(x) \) for all parameters \( x \).

Constrants on a division \( \beta \).

(1) \( \beta \supseteq \beta_0 \) where \( \beta_0 \) is the initial division, mapping each program input parameter to its given binding time and all other parameters to ?.
(2) \( \beta(x) = D \) if \( x \) is not of BSV.
(3) \( \beta(x) = D \) if the value of \( x \) depends on the value of some \( y \) with \( \beta(y) = D \).
(4) \( \beta(x) = D \) if \( x \) depends on the result of a residual call.

We now proceed to develop two principles that can be used to assign \( \beta(x) := S \), both using ideas from size-change termination.

4.7 Second and better try: Bounded Domination

A new principle for termination of offline program specialization:

Let \( \beta(x) = ? \) where \( \beta \) satisfies the constraints in Section 4.6. If no valid infinite call sequence causes \( x \) to increase infinitely, then \( x \) is of BSV.

This analysis goes considerably farther than the “call-free” method of Section 4.2. Further, it is relatively easy to implement applying familiar graph algorithms. First, define \( x \equiv w \) iff parameter \( x \) depends on \( w \) and \( w \) depends on \( x \), and define the equivalence class: \( [x] = \{w | x \equiv w \} \).

(a) Compute the closure \( \mathcal{S} \) of program \( p \)’s size-change graphs (now two-layered).
(b) Let \( \beta := \beta_0 \)
(c) Let \( \beta(x) := D \) for every \( x \) that depends on some \( y \) with \( \beta(y) = D \).
(d) Identify, as a candidate for upgrading, any \( x \) such that \( \beta(x) = ? \), and \( \beta(y) = S \) whenever \( x \) depends on \( y \notin [x] \).
(e) Reclassify all parameters \( z \in [x] \) by \( \beta(z) := S \) if no idempotent \( G \in \mathcal{S} \) contains \( w \xrightarrow{1} w \) for any \( w \in [x] \).

\[\text{We assume without loss of generality all functions have distinct parameter names, and that the program contains no calls to its initial function.}\]

\[\text{Note that } x \text{ must be potentially static, by Constraint 6.}\]
(f) Iterate Steps 31 and 32 to stability.

(g) Change remaining ?'s in β to D.

Explanation: Steps 31 and 32 follow constraints 30 and 31. Steps 31 and 32 apply the bounded domination principle to classify some equivalence classes [x] as static. Step 33 follows constraint 32.

For double with static input, Step 33 changes initial \( \beta = [x \mapsto S, u \mapsto ?, v \mapsto?] \) into

\[ \beta = [x \mapsto S, u \mapsto S, v \mapsto?] \]

Ackermann specialization terminates by similar reasoning. Now consider the interpreter example of Figure 2 with initial

\[ \beta = [\text{prog} \mapsto S, d \mapsto D, e \mapsto ?, \text{ns} \mapsto ?, \text{vs} \mapsto ?, \text{pg} \mapsto ?, f \mapsto ?, x \mapsto?] \]

pg is clearly of BSV because it is copied in all calls and never changed (increased or decreased). Further, call sites 2, 3 and 5-10 only pass values to e from substructures of e or pg, so the values of e are always a substructure of the static input. Thus e is of BSV by the Bounded Domination principle and can be annotated “static” (even though at call site 4 its value can become larger from one call to the next.) This and constraint 32 of Section 4.1 gives:

\[ \beta = [\text{prog} \mapsto S, d \mapsto D, e \mapsto S, \text{ns} \mapsto ?, \text{vs} \mapsto D, \text{pg} \mapsto S, f \mapsto S, x \mapsto S] \]

On the other hand, call site 4 poses a problem: ns can increase, which (so far) will cause it to be annotated “dynamic.” This is more conservative than necessary, as the name list ns only takes on finitely many values when interpreting any fixed program pg.

4.8 Third and still better try: Bounded Anchoring

A still more general principle allows potentially static parameters that increase:

Suppose \( \beta(x) = ? \) and \( \beta(y) = S \) where \( \beta \) satisfies the constraints of Section 4.1. If every valid infinite call sequence cs that infinitely increases \( x \) also infinitely decreases \( y \), then \( x \) is of BSV.

The set of known BSV parameters can iteratively be extended by this principle, starting with ones given by Bounded Domination 4. Again, it is relatively easy to implement; just replace Steps 31 and 32 above by the following:

31) Identify, as a candidate for upgrading, any \( x \) such that \( \beta(x) = ? \), and \( \beta(y) = S \) whenever \( x \) depends on \( y \notin [x] \).

32) Reclassify parameters \( z \in [x] \) by \( \beta(z) := S \) if every idempotent \( G \in S \) containing \( w \mapsto w \) for some \( w \in [x] \) also contains \( y \mapsto y \) for some \( y \) with \( \beta(y) = S \).

For the double example, Step 32 allows changing \( \beta = [x \mapsto S, u \mapsto S, v \mapsto?] \) into

\[ \beta = [x \mapsto S, u \mapsto S, v \mapsto S] \]

\(^4\)In fact, the Bounded Domination principle can be seen as the special case of Bounded Anchoring where the set of call sequences that infinitely increase \( x \) is empty.

Program \( p ::= d_1 \ldots d_n \)
Def \( d ::= f \ x_1 \ldots x_n = e' \)
Expression \( e ::= k \mid x \mid \text{if } e_1 \text{ then } e_2 \text{ else } e_3 \mid b \ e_1 \ldots e_n \mid \text{if } e_1 \ldots e_n \)
\( k \in \text{Constant} \quad x \in \text{Varname} \quad c \in \text{CallSite} \)
\( b \in \text{Basefuncname} = \{ \text{car, cdr, cons, ...} \} \quad f \in \text{Funnname} \)

Fig. 4. Syntax for the first-order functional language treated by the analysis

In the interpreter example, the previous analysis shows that \( e \) and \( pg \) are of BSV. The remaining parameter \( ns \) can increase (call 4), but a call sequence \( \ldots \) with an \textit{in situ} increase of \( ns \) also has an \textit{in situ} decrease in \( e \). This implies \( ns \) cannot increase unboundedly and so is also of BSV. Conclusion (as desired):

\[
\beta = [\text{prog } \mapsto S, d \mapsto D, a \mapsto S, ns \mapsto S, vs \mapsto D, pg \mapsto S, f \mapsto S, x \mapsto S]
\]

The only dynamic parameter of function \texttt{eval} is \( vs \), so target programs obtained by specialization will be free of all source program syntax.

4.9 Specialization point insertion

The discussion above was rather quick and did not cover Constraint 1 of Section 4.6 which concerns the function unfolding policy to be used. The justification of the constraint is that the result of a residual call is not available at specialization time.

There is a clear danger of infinite specialization-time unfolding, for instance even in the double example. This can be prevented by doing no unfolding at all, but by Constraint 1 this could force other parameters to be dynamic.

A more liberal unfolding policy can be used, based upon a specialization-point insertion analysis to mark a limited set of call sites as specialization points, not to be unfolded. These should be as few as possible, just enough to prevent infinite loop unrolling. This is not explained here, since this section is already long enough. More details, and correctness proofs, are given in the following sections.

5. SEMANTIC FOUNDATIONS FOR TERMINATION ANALYSIS

As mentioned in Section 4.3 it is vital that the program transformations rest on a firm basis of the programming language semantics if the user is to trust the generated programs. In the following sections we will present these foundations and correctness proofs for the termination analysis.

5.1 Syntax and semantics

The analyses presented operate on a strict first-order functional language with the formal syntax definition shown in Figure 4. For a function \( f \) we write \( f^i \) for the \( i \)-th parameter of \( f \), and label each function call site with a unique label \( c \). \texttt{CallSite} is the set of labels in the program. The functions defined by definitions \( d_1, \ldots, d_n \) are referred to as \( f_1, \ldots, f_n \). The semantics for normal, strict evaluation of this language, shown in Figure 5 is quite standard; all base functions are assumed to terminate, possibly with an \texttt{error} value, for all input. Given a tuple \( \vec{v} \), \( v_i \) denotes the \( i \)-th component. We assume given a domain \texttt{Value} \( \ni v \) and a size relation \( \leq \in \texttt{Value} \times \texttt{Value} \) which makes \texttt{Value} well-founded. Furthermore, we make use

\[ E : \text{Expression} \rightarrow \text{Value}^* \rightarrow \text{Value} \cup \{\text{error}, \bot\} \]

\[ E = E_\text{w}([\text{fix}(\lambda f. f \mapsto \lambda v_1 \ldots v_m, E_\text{w}[E_f](v_1, \ldots, v_m), \ldots, f_n \mapsto \lambda v_1 \ldots v_k, E_\text{w}[E_f](v_1, \ldots, v_k)])]) \]

\[ E_\text{w}[f[k]]^\\vartheta = \text{value } k \]

\[ E_\text{w}[f[x]]^\\vartheta = v_i \]

\[ E_\text{w}[\text{if } e_1 \text{ then } e_2 \text{ else } e_3]^\\vartheta = \text{if } v'_1 \text{ then } v'_2 \text{ else } v'_3, \text{ where } v'_i = E_\text{w}[e_i]^\\vartheta \]

\[ E_\text{w}[b \ e_1 \ldots e_n]^\\vartheta = \text{apply } b \ v'_1 \ldots v'_n, \text{ where } v'_i = E_\text{w}[e_i]^\\vartheta \]

\[ E_\text{w}[f \ e_1 \ldots e_n]^\\vartheta = \phi \ f \ v'_1 \ldots v'_n, \text{ where } v'_i = E_\text{w}[e_i]^\\vartheta \]

Fig. 5. Normal evaluation semantics. Use of 'if' is strict in its first argument, and applications of functions \textit{apply} and \( \phi \) are strict, returning \( \bot \) or error if any of their arguments are \( \bot \) or error.

of the function \textit{value} : \textit{Constant} \( \rightarrow \text{Value} \) which perform conversions between expressions and values, and also the standard function \textit{domain} and range operators \textit{dom} and \textit{rg}. The function \textit{apply} : \textit{Basefunname} \( \rightarrow \text{Value}^* \rightarrow (\text{Value} \cup \{\text{error}\}) \) returns the value resulting from the application of a base function to its arguments.

Functions \textit{value} and \textit{apply} are assumed to terminate for any input.

In the ensuing text we will use the following notation:

\textit{Definition 5.1.1.} For any set \( A \) we define \( A^* \) to be the set of all finite sequences over \( A \); and \( A^\omega \) to be the set of all infinite sequences over \( A \); and \( A^{\omega \omega} = A^* \cup A^\omega \). We use the same notation: \( a_1 a_2 a_3 \ldots \) for elements of either \( A^* \) or \( A^\omega \), and write \( a = a_1 a_2 a_3 \ldots a_n \) for elements of \( A^\omega \).

\textit{Definition 5.1.2. (Call sequence)} A call sequence is any finite or infinite \( e \in \text{Callsite}^{\omega \omega} \). Call sequence \( c_1 c_2 \ldots \) is well-formed iff \( c_i \) labels a call to a function \( f \) whose body \( e^f \) contains the call labeled with \( c_{i+1} \).

\textit{Definition 5.1.3. (Program states and transitions)}

\textit{A state} is a pair \( (f, v) \in \text{Funname} \times \text{Value}^* \).

\textit{A state transition} \( (f, v) \xrightarrow{\vartheta} (g, u) \) is a pair of states connected by a call \( c \ g \ e_1 \ldots e_n \) in the body \( f^i \) of \( f \), such that \( u = (u_1, \ldots, u_m) \) and \( E_\text{w}[e_i]^\\vartheta = u_i \).

\textit{A state transition sequence} is a sequence \( \sigma = (f_0, v_0) \xrightarrow{\vartheta} (f_1, v_1) \rightarrow \cdots \) (finite or infinite), where \( (f_i, v_i) \xrightarrow{\vartheta} (f_{i+1}, v_{i+1}) \) is a state transition for each \( i = 0, 1, \ldots \).

\textit{The calls in a state transition sequence} \( c_1 c_2 \ldots \) are given by \textit{calls}(\( \sigma \)) = \( c_1 c_2 \ldots \).

\textit{The set of encountered values} for a state transition sequence \( \sigma \) is defined as

\[ \mathcal{V}(\sigma) = \left\{ (x, V) \mid x \text{ is } f^i(\theta), \text{i.e., parameter number } i \text{ of } f \wedge V = \{ v_i \mid \sigma = (f_0, v_0) \rightarrow \cdots \rightarrow (f_i, v) \rightarrow \cdots \} \right\} \]

In the following we assume given a fixed program \( p \).

5.2 Size-change descriptors and graphs

Recall Sections 3.3.1 [1] and 4.3. Our overall purpose is to detect sequences of infinitely descending parameter values (in order to establish termination), and to find
parameters of bounded variation (if statically computable, they can be computed at program specialization time).

The "must-decrease" and "may-increase" graphs $G = (G^\downarrow, G^\uparrow)$ are at the heart of size-change analysis. The edge labels in $G^\downarrow, G^\uparrow$ relate the size of an expression's value to the sizes of its parameters, so it is essential to know what information they convey, and how it relates to our purposes. More precisely:

We let $D^\downarrow = \{\downarrow, \downarrow\}$, $D^\uparrow = \{\uparrow, \downarrow\}$ be two sets of dependency labels and impose an ordering $\subseteq$ on the labels by $\downarrow \subseteq \downarrow \subseteq \downarrow \subseteq \downarrow \subseteq \downarrow \subseteq \uparrow$.

A dependency is such a label together with a parameter, with intuitive meanings:

$\downarrow(x)$ ‘definitely decreasing on $x$ and less than its value,’

$\downarrow(y)$ ‘definitely depending on $x$ and less than or equal to its value,’

$\uparrow(y)$ ‘possibly depending on $y$, and unbounded if $y$ is unbounded’

$\uparrow(y)$ ‘possibly depending on $y$, and greater than $y$ for unbounded $y$.’

We name the collections of such dependency sets:

$$\text{Dep}^\downarrow \overset{\text{def}}{=} \mathcal{P}(D^\downarrow \times \text{Varname}), \text{Dep}^\uparrow \overset{\text{def}}{=} \mathcal{P}(D^\uparrow \times \text{Varname})$$

Each expression can be assigned a set of decreasing and a set of increasing dependencies. For instance, when evaluating the expression $\text{cdr } x$, the resulting value is always less than the value of $x$, written as $\{\downarrow(x)\}$, no matter the value of $x$. The value of expression $x$ is always less than or equal to $z$, written as $\{\downarrow(z)\}$.

The set of increasing dependencies of $\text{cons } x \ y$ is $\{\uparrow(x), \uparrow(y)\}$ since its value is greater than the values of $x$ and $y$; and the set of decreasing dependencies of $\text{cons } x \ y$ is empty. The set of increasing dependencies of $x$ is $\{\uparrow(x)\}$ since its value is greater than or equal to $x$. The set of increasing dependencies of $\text{cdr } x$ is also $\{\uparrow(x)\}$, since its value will be unbounded if $x$'s value is unbounded.

The analyses presented in detail in Appendix B centers around two approximation operators

$$\mathcal{E}^\downarrow : \text{Expression} \rightarrow (\text{Dep}^\downarrow)^* \rightarrow \text{Dep}^\downarrow$$
$$\mathcal{E}^\uparrow : \text{Expression} \rightarrow (\text{Dep}^\uparrow)^* \rightarrow \text{Dep}^\uparrow$$

where $\mathcal{E}^\downarrow[e] = \Delta$ means: "$\Delta$ is a "must-decrease" description of the value of $e$, given size descriptions $\Delta$ of its free variables," and $\mathcal{E}^\uparrow[e] = \Delta$ means: "$\Delta$ is a "may-increase" description of the value of $e$, given size descriptions $\Delta$ of its free variables."

These operators must terminate on all expressions (so that the termination analysis can terminate), and return a set that describes correctly (but perhaps approximately) the size relation between the value of an expression (as computed by $\mathcal{E}$) and the values of its free parameters. For example we expect

$$\mathcal{E}^\downarrow[\text{cdr } x][(\downarrow(x))] = (\downarrow(x)), \mathcal{E}^\uparrow[\text{cons } x \ y][(\uparrow(x), (\uparrow(y))] = (\uparrow(x), \uparrow(y))$$

As $\downarrow$ is a stronger statement than $\downarrow$ and $\uparrow$ a stronger statement than $\downarrow$ we remove $\downarrow(x)$ from sets containing $\uparrow(x)$ and $\downarrow(x)$ from sets containing $\uparrow(x)$.

Now that we are able to relate the size of an expression value to the sizes of its free variables, we are able to construct the size-change graphs that represent the

$\mathcal{P}$ is the power set operator: $\mathcal{P}(X) = \{Y \mid Y \subseteq X\}$.
size changes of the function parameters from one call to another. They are formally given by

**Definition 5.2.1. (Size-change graphs)**

—A size-change graph is a pair \( G = (G^i, G^v) \), usually written \( G = \begin{bmatrix} G^i \\ G^v \end{bmatrix} \), where \( G^i = (\text{var}(f), \text{var}(g), E) \) is a bipartite graph with edges \( E \subseteq \text{var}(f) \times D^u \times \text{var}(g) \). Often, we will draw a graphical representation of size change graphs like this example:

\[
\begin{array}{c}
G^i \\
\begin{array}{c}
x \longrightarrow u \\
y \longrightarrow v \\
z \longrightarrow w \\
\end{array}
\end{array}
\begin{array}{c}
G^v \\
\begin{array}{c}
x \longrightarrow u \\
y \longrightarrow v \\
z \longrightarrow w \\
\end{array}
\end{array}
\]

where \( \Downarrow \) and \( \Uparrow \) labels have been omitted for readability. We will also refer to \( G^i \) and \( G^v \) as size-change graphs.

—Given a call site \( c : g e_1 \ldots e_n \) in a function \( f \), we define \( G_c = \begin{bmatrix} G^i_c \\ G^v_c \end{bmatrix} \), where

\[
G^i_c = (\{f^{(1)}, \ldots, f^{(m)}\}, \{g^{(1)}, \ldots, g^{(n)}\}, E^i_c)
\]
\[
G^v_c = (\{f^{(1)}, \ldots, f^{(m)}\}, \{g^{(1)}, \ldots, g^{(n)}\}, E^v_c)
\]
\[
E^i_c = \{ f^{(i)} \xrightarrow{\phi} g^{(j)} \mid \delta(f^{(i)}) \in E^i_c \land f^{(j)} \}
\]
\[
E^v_c = \{ f^{(i)} \xrightarrow{\phi} g^{(j)} \mid \delta(f^{(i)}) \in E^v_c \land f^{(j)} \}
\]

—in the ensuing text, we let \( \mathcal{G} \) denote the set of size-change graphs for program \( p \), defined by

\[
\mathcal{G} = \{ G_c \mid c : g e_1 \ldots e_n \text{ is a call in } p \}
\]

5.3 Informal safety discussion

To illustrate the meanings of the size descriptions, here are some possible sets the size approximation operators could yield, where \( \Delta_{id} = (\{\delta(x_1)\}, \ldots, \{\delta(x_n)\}) \) is the identity “must-decrease” description, and \( \Delta_{id} = (\{\underline{\delta}(x_1)\}, \ldots, \{\underline{\delta}(x_n)\}) \) is the
identity “may-increase” description\[10\]

<td>${\downarrow(x_1), \downarrow(x_2)}$</td>
</tr>
</tbody>
</table>

The ‘$\downarrow$’ in the sets generated by $\mathcal{E}^i$ is read as ‘and,’ while the ‘$\updownarrow$’ in the sets generated by $\mathcal{E}^o$ is read as ‘or.’ The informal interpretation of the approximation sets are

- $\{\}$: no size-change information is given
- $\{\downarrow(x_1)\}$: the value of $e$ is definitely less than the value of $x_1$
- $\{\downarrow(x_1)\}$: the values of $e$ may be unbounded, if the values of $x_1$ are unbounded
- $\{\downarrow(x_1), \downarrow(x_2)\}$: the value of $e$ is no greater than that of $x_1$ and no greater than that of $x_2$
- $\{\downarrow(x_1), \updownarrow(x_2)\}$: the value of $e$ may exceed that of $x_1$ or $x_2$ for infinitely many values of $x_1$ or $x_2$
- $\{\downarrow(x_2), \updownarrow(x_3)\}$: the values of $e$ may be unbounded if the values of $x_2$ are unbounded; and may exceed $x_3$ for infinitely many $x_3$
- $\{\downarrow(x_1), \downarrow(x_2)\}$: the values of $e$ may be unbounded for unbounded values of $x_1$ or $x_2$.

Principles. Safety of the “must-decrease” analysis $\mathcal{E}^i$ is easier to define, and rather simpler to implement than $\mathcal{E}^o$. For any expression $e$, $\mathcal{E}^i[e]$ will depend on the parameters seen in $e$, and the operators applied to them. For example, $\mathcal{E}^i[\text{cons } e_1 e_2] = \{\}$, and

$$\mathcal{E}^i[\text{cdr } e] = \{\downarrow(x) \mid \exists(x) \in \mathcal{E}^i[e] \text{ or } \downarrow(x) \in \mathcal{E}^i[e]\}$$

For details, see Figure 13 in Appendix 12.

The purpose of $\mathcal{E}^i$ is to detect expression behavior that is guaranteed always to decrease values, while $\mathcal{E}^o$ detects expression behavior that might increase values without bounds. Note that according to the concept of safety defined below, the sets of decreasing operators can safely be reduced and weakened: For instance, the expression $\{\downarrow(x_2)\}$ above could be approximated by $\{\downarrow(x_2)\}$ or $\{\}$. Correspondingly, sets of increasing operators can safely be extended and exaggerated: the expression $\text{if } x_1 \text{ then car } x_2 \text{ else cdr } x_2$ could also be approximated by $\{\downarrow(x_1), \downarrow(x_2)\}$—or

\[10\text{Subsequently we will very often use the identity descriptions, so we will sometimes just write } \mathcal{E}^i[e] \text{ or } \mathcal{E}^o[e], \text{ omitting } \Delta^i_{id}, \Delta^o_{id}.\]
even \( \uparrow(x_1), \uparrow(x_2) \). However, although these changes are safe, they will degrade the precision of the termination analysis.\(^\text{17}\)

The approximation operators we have used for the implementation and experiments of Section 5 and proof of their safety are given in Appendix 9. These operators yield rather crude approximations, but can easily be replaced by other and more precise safe approximation if desired, as long as they satisfy the safety conditions.

5.4 Safe "must-decrease" size approximations

**Definition 5.4.1. (Safety of \( \mathcal{E}^\downarrow \))** A decreasing size approximation operator \( \mathcal{E}^\downarrow \) is called safe iff both the following are true for all \( e \in \text{Expression} \) and any infinite set of environments \( \{v_1, v_2, \ldots \} \): Suppose \( \mathcal{E}[e][v_1] = w_1, \mathcal{E}[e][v_2] = w_2, \ldots \) Then

1. if \( \downarrow(x_i) \in \mathcal{E}^\downarrow[e] \) then for all \( k, w_k \notin \{\text{error}, \bot\} \) implies \( w_k \leq v_{ki} \)
2. if \( \uparrow(x_i) \in \mathcal{E}^\downarrow[e] \) then for all \( k, w_k \notin \{\text{error}, \bot\} \) implies \( w_k < v_{ki} \)

The safety of \( \mathcal{E}^\downarrow \) is simple because we require that it give definite information on what the size of the value of an expression is, every time it is evaluated. Further, it is easily defined compositionally, so \( \mathcal{E}^\downarrow[e_1, \ldots, e_n] \Delta \) is expressed only in terms of \( \mathcal{E}^\downarrow[e_1] \Delta, \ldots, \mathcal{E}^\downarrow[e_n] \Delta \).

5.5 Safe "may-increase" size approximations

For "may-increase" dependencies \( \downarrow(x) \) or \( \uparrow(x) \), one of two cases could apply:

1. \( e \)'s value is of unbounded variation, provided \( x \) is of unbounded variation. Example: \( e = x \), or \( e = \text{cdr } x \) both have dependency \( \downarrow(x) \).
2. the value of \( e \) exceeds the value of \( x \) infinitely often. Example: \( e = \text{cons } x \ y \) has dependency \( \uparrow(x) \).

In this section we begin with plausible but inadequate definitions of safety of "may-increase" analysis, and then show examples to illustrate the subtlety of how to give program descriptions that are safe with respect to these informal readings. We examine the definitions' shortcomings, refine them, and end with a solid definition of safety of an analysis.

**First try at "may-increase" size approximation.** We adapt Definition 5d.1

**Trial definition 1 (Safety of \( \mathcal{E}^\uparrow \))** An increasing size approximation operator \( \mathcal{E}^\uparrow \) is called safe iff both the following are true for all \( e \in \text{Expression} \) and any finite set of environments \( \{v_1, v_2, \ldots \} \): Suppose \( \mathcal{E}[e][v_1] = w_1, \mathcal{E}[e][v_2] = w_2, \ldots \) Then

\(^{17}\)The expression if \( \text{length } x_1 < 42 \) then \( x_1 \) else \( \text{cons } 17 \ 19 \) can in fact be given a more precise increasing size approximation, namely the empty set, because by inspecting the if-condition it can be seen that the length of the resulting value is bounded.

Similarly, the expression if \( \text{length } x_1 < \text{length } x_2 \) then \( x_1 \) else \( \text{cdr } x_2 \) can be approximated more precisely by the decreasing dependency set \( \{\downarrow(x_1), \downarrow(x_2)\} \), which reads 'the value of \( e \) is definitely not greater than that of \( x_1 \), and definitely less than that of \( x_2 \). Note also that either \( \downarrow(x_1) \) or \( \downarrow(x_2) \) (but not both!) could be omitted from the increasing dependency set of this expression, because unbounded increase of the omitted parameter is only possible if the remaining parameter is increased as well. This also implies that in general no "best" size approximation exists.

(1) if for all \( k, w_k \notin \{\text{error}, \perp\} \) implies \( w_k \geq v_{kt} \), then \( \downarrow(x_i) \in \mathcal{E}^l[e] \)

(2) if for all \( k, w_k \notin \{\text{error}, \perp\} \) implies \( w_k > v_{kt} \) then \( \uparrow(x_i) \in \mathcal{E}^l[e] \)

**Two problems.** The safety of \( \mathcal{E}^l \) is complicated by two facts. First, a description \( \downarrow(x) \) by part (1) above does not capture the requirement that unbounded \( x \) implies unbounded \( e \), e.g., \( e \equiv \text{cdr } x \) should have description \( \downarrow(x) \).

Another problem is that an expression need not be classified as "increasing" if its value is greater than its arguments for only a finite set of argument values: Consider the function

\[
\text{lookupbody } f \; p = \begin{cases} 
\text{nil} & \text{cons 'error: (cons 'undefined (cons 'function nil))} \\
\text{else if } f = \text{caar } p & \text{then caddr } p \\
\text{else lookupbody } f \; (\text{cdr } p)
\end{cases}
\]

The value of \( \text{lookupbody } f \; p \) might be longer than the value of \( f \) or \( p \), due to the first if branch. However, if we classify it as \( \{\uparrow(f), \uparrow(p)\} \) we will not be able to detect that parameter \( e \) in the interpreter example of Figure 2 is of bounded variation, as \( e \) would seem to be increasingly dependent on itself at call site \( \mathcal{O} \). The point is though that even if this expression participates in a program loop where the length of \( f \) or \( p \) increases, the length of its value will always be bounded by \( p \), and we need only classify it as \( \{\downarrow(p)\} \).

We now try to remedy these problems:

**Trial definition 2 (Safety of \( \mathcal{E}^l \))** An increasing size approximation operator \( \mathcal{E}^l \) is called **safe** iff both the following are true for all \( e \in \text{Expression} \) and any infinite set of environments \( \{v_1, v_2, \ldots\} \): Suppose \( \mathcal{E}[e]v_1 = w_1, \mathcal{E}[e]v_2 = w_2, \ldots \) and every \( w_i \notin \{\text{error}, \perp\} \). Then

(1) if \( |\{v_{ji}\}| = \infty \) and \( |\{w_{ji}\}| = \infty \), then \( \downarrow(x_i) \in \mathcal{E}^l[e] \).

(2) if \( |\{v_{ji}\}| = \infty \) and \( |\{j|w_j > v_{ji}\}| = \infty \), then \( \uparrow(x_i) \in \mathcal{E}^l[e] \).

**Bounded variation.** The familiar program:

\[
double \; x \; = \; \text{dblplus } x \; 0 \\
\text{dblplus } u \; v \; = \; \text{if } u \leq 0 \; \text{then } v \; \text{else } \text{dblplus } \; (u - 1) \; (v + 2)
\]

is a subtle "may-increase" example involving unboundedness. Safe size descriptions of \( u - 1 \) and \( v + 2 \) are clearly \( \downarrow(u) \) and \( \uparrow(v) \). Finding a safe size description of a call \( \text{dblplus } u \; v \) involves finding the net effect of calling function \( \text{dblplus} \). The appropriate safe description of \( \text{dblplus } u \; v \) is \( \{\uparrow(u), \uparrow(v)\} \), which leads to the expected \( \{\uparrow(x)\} \) as size description of \( \text{double } x \) (consistent with our a priori knowledge of the effect of double).

At first sight description \( \{\uparrow(u), \uparrow(v)\} \) seems strange, since the value of \( \text{dblplus } u \; v \) is computed from \( v \) alone (by adding \( 2 \) repeatedly). However the number of times \( 2 \) is added depends on \( u \). Consequence: if either \( u \) or \( v \) is unbounded, then the value of \( \text{dblplus } u \; v \) will also be unbounded.

We desire result description \( \mathcal{E}^l[\text{dblplus } u \; v]([\Delta_{id}]) = \{\uparrow(u), \uparrow(v)\} \). Unfortunately this cannot be obtained compositionally: The recursive call gives \( \mathcal{E}^l[u - 1][\Delta_{id}] = \{\downarrow(u)\}, \mathcal{E}^l[v + 2][\Delta_{id}] = \{\uparrow(v)\} \) and the \( \text{dblplus} \) result value equals
$v$’s final value—so the indirect dependency of the value of $\texttt{dblplus } u v$ on $u$ is not registered at all.

A second idea is to account for indirect dependencies. Notation: for any tuple $\vec{v} = (v_1, \ldots, v_n)$ of values of $e$’s free variables, let $\overleftarrow{\vec{v}_j = u}$ be $\vec{v}$ after replacing the $j$-th component by $u$. The following is formulated more simply, in terms of variations on a given tuple rather than infinite sequences of tuples.

Intuitively, $\overleftarrow{\mathcal{E}}$ is safe if for all $i$ we have that $\mathcal{E}(x_i) \in \overleftarrow{\mathcal{E}[e]}\overleftarrow{\vec{v}}$ if there is a tuple $\vec{v}$ such that the value of $e$ is greater than $v_i$ for infinitely many $v_i$, keeping the remaining parameters in $\vec{v}$ fixed. This could be stated formally by the following

**Trial definition 3 (Safety of $\overleftarrow{\mathcal{E}}$)** An increasing size approximation operator $\overleftarrow{\mathcal{E}}$ is called safe iff both the following are true for all $e \in \mathcal{E}$:

1. If there exists $\vec{v} = (v_1, \ldots, v_n) \in \mathcal{V}$ such that for all $K \in \mathcal{V}$

$$\overleftarrow{\mathcal{E}[e]}\overleftarrow{\vec{v}_j = v} = v' \neq \bot \land v > K$$

then $\mathcal{E}(x_i) \in \overleftarrow{\mathcal{E}[e]}\overleftarrow{\vec{v}}$.

2. If there exists $\vec{v} = (v_1, \ldots, v_n) \in \mathcal{V}$ such that

$$\overleftarrow{\mathcal{E}[e]}\overleftarrow{\vec{v}_j = v} = v' \neq \bot \land v > v'$$

then $\mathcal{E}(x_i) \in \overleftarrow{\mathcal{E}[e]}\overleftarrow{\vec{v}}$.

This overcomes the two preceding problems (constants, and dependence of $\texttt{dblplus } u v$ on $u$).

However, we wish the approximation to be safe for all cases, including cases like $e \equiv 1 + \min x_1 x_2$, where $\mathcal{E}[e](v_1, v_2) > v_1$ for only finitely many $v_1$ when $v_2$ is fixed but $\mathcal{E}[e](v_1, v_2) > v_2$ for infinitely many $v_1$ if $v_1$ and $v_2$ are increased together. In this case $\mathcal{E}(x_1)$ or $\mathcal{E}(x_2)$ must be in $\overleftarrow{\mathcal{E}[e]}\overleftarrow{\vec{v}}$; otherwise $\overleftarrow{\mathcal{E}[e]}\overleftarrow{\vec{v}}$ would not reflect the fact that the value of $e$ is greater than that of $x_1$ or $x_2$ for infinitely many $(x_1, x_2)$. This is captured by considering all subsets of the parameters.

For given $\vec{v} \in \mathcal{V}$ and $X \subseteq \{x_1, \ldots, x_n\}$ we define the set $V(\vec{v}, X) = \{(u_1, \ldots, u_n) | \text{if } x_i \in X \text{ then } u_i \in \mathcal{V} \text{ else } u_i = v_i\}$, that is, fixing the values of all parameters except those mentioned in $X$.

**Definition 5.5.1. (Safety of $\overleftarrow{\mathcal{E}}$)** An increasing size approximation operator $\overleftarrow{\mathcal{E}}$ is called safe iff both the following conditions are true for all $e \in \mathcal{E}$ and $X \subseteq \{x_1, \ldots, x_n\}$, where $\{x_1, \ldots, x_n\}$ are the parameters of the function in which $e$ occurs:

1. If for all $K \in \mathcal{V}$ there exists $\vec{v} = (v_1, \ldots, v_n) \in \mathcal{V}$ such that

$$\mathcal{E}[e]\overleftarrow{\vec{v}} = v' \neq \bot \land v > K$$

then $\mathcal{E}(x_i) \in \overleftarrow{\mathcal{E}[e]}$ for some $x_i \in X$ and $\delta \in \{\bot, \Delta\}$.

2. For all $x_j \in X$, if there exists $\vec{v} = (v_1, \ldots, v_n) \in \mathcal{V}$ such that

$$\mathcal{E}[e]\overleftarrow{\vec{v}} = v' \neq \bot \land v > v'$$

then $\mathcal{E}(x_i) \in \overleftarrow{\mathcal{E}[e]}$ for some $x_i \in X$. 

5.6 Size-change graphs and multipaths

Definition 5.6.1. (Multipath) Given a well-formed call sequence \( cs = c_1c_2 \ldots \), multipath \( \mathcal{M}(cs) \) is the sequence \( G_{c_1}, G_{c_2}, \ldots \) of size change graphs. Given a multipath \( \mathcal{M} = G_1, G_2, \ldots \), we often consider only the increasing or decreasing part \( \mathcal{M}^\delta = G_1^\delta, G_2^\delta, \ldots \) for \( \delta \in \{\uparrow, \downarrow\} \).

A multipath can be viewed as one big graph obtained by concatenating the size-change graphs:

\[
\mathcal{M} = \begin{cases} 
\mathcal{M}^\uparrow = \begin{array}{c}
G_1^\uparrow \\
G_2^\uparrow \\
G_3^\uparrow \\
\end{array} \\
\mathcal{M}^\downarrow = \begin{array}{c}
G_1^\downarrow \\
G_2^\downarrow \\
G_3^\downarrow \\
\end{array}
\end{cases}
\]

Thus, we make the following

Definition 5.6.2. (Multipath subgraph)

—We define a subgraph of a multipath \( \mathcal{M} \) (or \( \mathcal{M}^\delta \)) to be a connected subgraph of the graph created by the concatenation of the size-change graphs.

—A maximal subgraph is a subgraph \( \tilde{G} \) that is not a subgraph of any other subgraph \( \tilde{G} \neq \tilde{G} \).

—The length of a subgraph is the length of the longest directed path in the subgraph (possibly infinite).

Multipaths can be used not only to describe size relations between program parameters, but also to describe an actual computation. Without causing ambiguity, we can overload the \( \mathcal{M} \) operator:

Definition 5.6.3. (State transition multipath) Given a state transition sequence \( \sigma = (f_0, \vec{v}_0) \xrightarrow{c_1}(f_1, \vec{v}_1) \xrightarrow{c_2}(f_3, \vec{v}_3) \xrightarrow{c_3} \ldots \), we let \( \mathcal{M}(\sigma) \) denote the multipath \( G_1^\sigma, G_2^\sigma, \ldots \), where each \( G_k^\sigma \) is obtained from \( G_k^\varepsilon \) by replacing the parameters by their actual values (given by \( \vec{v}_{k-1} \) and \( \vec{v}_k \)), removing all the edges, and then adding new edges \( v_{(k-1)i} \xrightarrow{\uparrow} v_{kj} \) whenever \( v_{(k-1)i} > v_{kj} \) and \( v_{(k-1)i} \xrightarrow{\downarrow} v_{kj} \) whenever \( v_{(k-1)i} = v_{kj} \).
Termination Analysis and Specialization-Point Insertion in Partial Evaluation · 135

One multipath $\mathcal{M}(\sigma)$ with $\text{calls}(\sigma) = c_1c_2\ldots$ from the preceding example in might look like this:

$$
\mathcal{M}(\sigma) = \begin{array}{c}
1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & \cdots \\
\end{array}
\begin{array}{c}
G_1^\sigma & G_2^\sigma & G_3^\sigma
\end{array}
$$

where any $\downarrow$ labels have been omitted for readability.

Note that there is a bijective correspondence between the nodes of $\mathcal{M}(\sigma)$ and $\mathcal{M}^\downarrow(c_\sigma)$, where $c_\sigma = \text{calls}(\sigma)$. In the following, we will therefore consider them identical, and speak about the value of a node $n$ in $\mathcal{M}^\downarrow(c_\sigma)$, meaning the value of the corresponding node in $\mathcal{M}(\sigma)$. Further, the safety definition of $\mathcal{E}^\downarrow$ (cf. Definition 5.4.1) implies the following lemma for the arcs:

**Lemma 5.6.4. (Arc correspondence for $\mathcal{M}^\downarrow$)** Given state transition sequence $\sigma = (f_0, v_0)$$\xrightarrow{c_\sigma} \cdots$, if there is an arc $n \xrightarrow{\delta} n'$ in $\mathcal{M}^\downarrow(c_\sigma)$, where $c_\sigma = \text{calls}(\sigma)$, there is a similar arc $v \xrightarrow{\delta'} v'$ in $\mathcal{M}(\sigma)$ between the values corresponding to $n$ and $n'$. Furthermore, if $\delta = \downarrow$ then $\delta' = \downarrow$.

**Definition 5.6.5. (Threads)** Given a multipath $\mathcal{M}$, a thread is a subgraph in which each node has at most one ingoing and one outgoing arc.

Combining this definition with Lemma 5.6.4, we obtain

**Corollary 5.6.6. (Thread correspondence)** If $\mathcal{M}^\downarrow(c_\sigma)$ has a thread $\tau$ with $\mathcal{M}$ $\downarrow$-labels and $c_\sigma = \text{calls}(\sigma)$, then $\mathcal{M}(\sigma)$ has a corresponding thread $\tau'$ with at least $\mathcal{M}$ $\downarrow$-labels.

A multipath $\mathcal{M}^\downarrow(c_\sigma)$ conveys information about the boundedness of the corresponding values in $\mathcal{M}(\sigma)$:

**Lemma 5.6.7. (Unbounded predecessors)** Given a state transition sequence $\sigma$ with call sequence $c_\sigma$, there exists a $K$ such that if a sequence of nodes $n_1, n_2, \ldots$ in $\mathcal{M}(\sigma)$ has an unbounded sequence of values $v_1, v_2, \ldots$ all greater than $K$, there exist infinitely many of these nodes $n_{k_1}, n_{k_2}, \ldots$ which have at least one immediate predecessor $p_{k_1}, p_{k_2}, \ldots$, and the sequence of values $w_{k_1}, w_{k_2}, \ldots$ of the nodes in $\mathcal{M}(\sigma)$ corresponding to these predecessors will be unbounded and greater than $K$.

Furthermore, for all $j$, if there is no arc $p_{k_j} \xrightarrow{\downarrow} n_{k_j}$, then $w_{k_j} > v_{k_j}$.

**Proof.** Given this $\sigma$, assume the sequence $v_1, v_2, \ldots$ is unbounded, and consider the set of the size-change graphs in $\mathcal{M}^\downarrow(c_\sigma)$ that contain nodes $n_1, n_2, \ldots$ as right-side elements:

$$
G_1^\sigma \quad G_2^\sigma \quad G_k^\sigma
$$

As $G$ is finite, there must exist at least one $G^\delta$, with a right-side node $n$, and an infinite subsequence $k_1, k_2, \ldots$ for which $G^\delta = G^\delta_{k_1} = G^\delta_{k_2} = \ldots$, where $v_{k_1}, v_{k_2}, \ldots$ is unbounded.

For each such $G^\delta$, all of these values are computed by the same expression $e$, based on (a subset of) the values of the constants found in the program text, and the values of the immediately preceding nodes, i.e. the left-hand nodes in $G^\delta$. For any $K$, there are infinitely many $v_{k_1} > K$, and as the computation of the expression is deterministic, this is only possible if some parameter $x_{v'}$ in $e$ takes on infinitely many different values $w^1, w^2, \ldots$, so by the second criterion of the safety of $E^\delta$ (cf. Definition 5.5.1), $\delta(x_{v'}) \in E^\delta[e]$ for some $\delta \in \{\uparrow, \downarrow\}$, which implies that there exists an arc $x_{v'} \xrightarrow{\delta} n_{k_1}$ in $G^\delta$.

Finally, if there exist infinitely many $w^1_{k_1}$ for which $w^1_{k_1} < v_{k_1}$ for some $x_{v'}$, the first criterion of the safety of $E^\delta$ requires that the arc $x_i \xrightarrow{\delta} n_{k_1}$ be labeled $\delta = \uparrow$ for some $x_i$ (possibly $i = i'$) whose sequence of values $w_1, w_2, \ldots$ is unbounded. So the desired predecessors are the (infinitely many) nodes $p_{k_1}, p_{k_2}, \ldots$ corresponding to $x_i$ for which $w_{k_1} \geq v_{k_1}$.

**Definition 5.6.8.** *(Origin node)* A node in a multipath $M^\delta$ which has no predecessors is called an origin node.

Given this definition, a consequence of the contraposition of Lemma 5.6.7 is the following

**Corollary 5.6.9.** *(Origin node boundedness)* Given a state transition sequence $\sigma$ with call sequence $cs$, there exists a value $K$ such that for any origin node in $M^\delta(cs)$, the value of the corresponding node in $M(\sigma)$ is bounded by $K$.

We now use this corollary and the preceding lemma to show that obtaining a sequence of unbounded values in a state transition sequence $\sigma$ requires that there exist paths with unboundedly many $\uparrow$-labeled arcs in $M^\delta(cs)$:

**Lemma 5.6.10.** Let a state transition sequence $\sigma$ be given with call sequence $cs$ and assume for any $K$ there exists a set of finite subgraphs $G_1, G_2, \ldots$ of $M(\sigma)$ such that for each subgraph $G_k$ there exists a right hand node $n_k$ in the final (rightmost) size change graph, where the sequence of values of $n_1, n_2, \ldots$ is unbounded and greater than $K$.

Then it follows for any $M \in \mathbb{N}$ that there exists $k \in \mathbb{N}$ such that there is a path $\xrightarrow{\delta} \ldots \xrightarrow{\delta} n_k$ in $G^\delta_k$, the graph in $M^\delta(cs)$ corresponding to $G_k$, which has at least $M \uparrow$ labels.

**Proof.** by induction on $M$: For $M = 0$, the lemma is trivially true.

For $M > 0$, choose $K$ greater than the upper bound on the origin nodes such that it satisfies Lemma 5.6.7. That lemma then states that for infinitely many $k_j$ there exist predecessors $p_{k_j}$ of $n_{k_j}$ where the sequence of values of $p_{k_1}, p_{k_2}, \ldots$ is unbounded. If infinitely many arcs $p_{k_j} \xrightarrow{\delta} n_{k_j}$ in $M^\delta(cs)$ are labeled $\delta = \uparrow$, the induction hypothesis proves the desired property.

Otherwise, we proceed as follows: For each $k_j$ where the arc is labeled $\uparrow$, we change $G_{k_j}$ by removing the final size change graph. This way, we get a new sequence $G_1, G_2, \ldots$ where some of the subgraphs are shorter than the original.
ones. Further, Lemma 5.6.1 ensures that for each subgraph, either the final size change graph in $M^i(c_s)$ contains an arc labeled $\uparrow$, or there exists a right hand node $n_k$, where the sequence of values of $n_1, n_2, \ldots$ is unbounded and greater than $K$.

This procedure is applied repeatedly, and there are two possibilities: Either we stop after finitely many iterations when infinitely many of the subgraphs end with a size change graph that has a corresponding $\uparrow$-labeled arc in $M^i(c_s)$. Otherwise, the process continues indefinitely, and as each subgraph, as well as $G$, is finite, this produces an infinite sequence of subgraphs where each final size change graph has a corresponding $\uparrow$-labeled arc in $M^i(c_s)$ (because the value of node $n_k$ is greater than $K$, preventing it from being an origin node). An example of this process for subgraphs composed of three size change graphs $G_1, G_2, G_3$ whose corresponding graphs in $M^i(c_s)$ have no $\uparrow$-arcs and some which do have $\uparrow$-arcs, commonly denoted $\bar{G}$, is shown in Figure 6 (the size change graphs that are removed in each step are marked with boxes). Finally, the induction hypothesis proves the desired property.

Lemma 5.6.11. Given a state transition sequence $\sigma$, assume for any $M'$ that there exists a subgraph in $M^i(c_s)$ that has a path $\rightarrow \uparrow \rightarrow \cdots \rightarrow x$ with at least $M'$ $\uparrow$ labels. Then for any $M$ there exists a parameter $x$ and a subgraph in $M^i(c_s)$ with a path $x \rightarrow \uparrow \rightarrow \cdots \rightarrow x \rightarrow \uparrow \rightarrow \cdots \rightarrow x$ that passes through $x$ at least $M$ times. Furthermore, each subpath $x \rightarrow \uparrow \rightarrow \cdots \rightarrow x$ of this path has at least one $\uparrow$ label.

Proof. Let $N$ be the number of parameters in $p$. A path with at least $N$ $\uparrow$ labels will contain at least one path $x \rightarrow \cdots \rightarrow x$ for some parameter $x$, and it follows that choosing a path with at least $MN$ $\uparrow$ labels will contain the desired path.

Definition 5.6.12. (Size-change graph composition) Given two size-change graphs $G_1 = (\text{var}(f), \text{var}(g), E_1)$ and $G_2 = (\text{var}(g), \text{var}(h), E_2)$, we define their composition by $G_1 \circ G_2 = (\text{var}(f), \text{var}(h), E)$, where $x_i \xrightarrow{\gamma} z_k \in E$ iff $(x_i \xrightarrow{\delta_1} y_j) \in E_1$ and $(y_j \xrightarrow{\delta_2} z_k) \in E_2$, and

$$\gamma = \begin{cases} \uparrow, & \text{if } \delta_1 = \uparrow \lor \delta_2 = \uparrow \\ \downarrow, & \text{if } \delta_1 = \downarrow \land \delta_2 = \downarrow \\ \uparrow, & \text{if } \delta_1 = \downarrow \lor \delta_2 = \uparrow \\ \downarrow, & \text{if } \delta_1 = \uparrow \land \delta_2 = \downarrow \end{cases}$$

For $G_1 = \begin{bmatrix} G_1^i \\ G_1^e \end{bmatrix}$ and $G_2 = \begin{bmatrix} G_2^i \\ G_2^e \end{bmatrix}$ we define $G_1; G_2 = \begin{bmatrix} G_1^i; G_2^i \\ G_1^e; G_2^e \end{bmatrix}$.

Definition 5.6.13. For a well-formed nonempty call sequence $c_s = c_1 \ldots c_n$, we define the size-change graph for $c_s$, denoted by $G_{c_s}$, as $G_{c_1}; \ldots; G_{c_n}$.

It is straightforward to show that composition is associative. Furthermore, the arcs in the composition are an approximation of the threads in the composed size-change graphs.
\[
\begin{align*}
\hat{G}_1 &= \hat{G} \ G_1 \ G_2 \\
\hat{G}_2 &= \hat{G} \ G_3 \ G_1 \ G_1 \\
\hat{G}_3 &= \hat{G} \ G_2 \ G_3 \ G_1 \ G_1 \\
\hat{G}_4 &= \hat{G} \ G_1 \ G_3 \ G_2 \ G_2 \ G_2 \\
\hat{G}_5 &= \hat{G} \ G_2 \ G_3 \ G_1 \ G_3 \ G_1 \ G_1 \\
\hat{G}_6 &= \hat{G} \ G_2 \ G_1 \ G_3 \ G_2 \ G_3 \ G_2 \ G_2 \\
\hat{G}_7 &= \hat{G} \ G_3 \ G_1 \ G_3 \ G_2 \ G_2 \ G_2 \ G_2 \\
\hat{G}_8 &= \hat{G} \ G_2 \ G_1 \ G_3 \ G_2 \ G_3 \ G_2 \ G_2 \ G_2 \\
\hat{G}_9 &= \hat{G} \ G_3 \ G_1 \ G_3 \ G_2 \ G_2 \ G_2 \ G_2 \ G_2 \\
\hat{G}_{10} &= \hat{G} \ G_2 \ G_1 \ G_3 \ G_2 \ G_3 \ G_2 \ G_2 \ G_2 \ G_2 \\
\end{align*}
\]

Fig. 6. Generating a sequence with infinitely many subgraphs ending in a \( \hat{G} \) graph. In each step we remove the same last, non-\( \hat{G} \) size-change graph from infinitely many subgraphs.
Lemma 5.6.14. (Composition soundness) \( G_1; \ldots; G_n \) has an arc \( x \xrightarrow{\delta} u \) iff there is a thread \( x \rightarrow \cdots \rightarrow u \) all the way along multipath \( M = G_1, \ldots, G_n \). Furthermore, \( \delta = \uparrow \) or \( \delta = \downarrow \) iff there is a thread with at least one \( \uparrow \) or \( \downarrow \) label, respectively.

Proof. by induction on \( n \), using the definition of composition.

6. QUASITERMINATION ANALYSIS

Now that we have defined the size-change graphs that express parameter changes along a call sequence, we can reason about the termination properties of all possible call sequences during evaluation. We start by defining some properties of the program parameters that describe quasitermination, originally proposed by Holst [1991], in which the program might not terminate, but the parameters will only take on a bounded set of values during any program run.

6.1 Quasitermination definitions

Definition 6.1.1. (Bounded Variation) For any state transition sequence \( \sigma \) the function \( \text{bounded}(\sigma) = \{ x \mid (x, V) \in \gamma(\sigma) \land |V| < \infty \} \) defines the set of parameters of bounded variation of that transition sequence. A parameter \( x \) is said to be of bounded variation, written \( BV(x) \), iff \( x \in \text{bounded}(\sigma) \) for all \( \sigma \).

Considering Definition 6.1.1 we get the following

Lemma 6.1.2. (Quasitermination) Program \( p \) is quasiterminating iff all program parameters are of bounded variation.

6.2 Quasitermination detection

We now employ a division \( \beta : \text{Varname} \rightarrow \{ S, ? \} \) for dividing the parameters into definitely of bounded variation (\( \bar{S} \)) or as yet undecided (?). A division that ensures termination is then constructed in the following way: First we classify all parameters as \( \beta_0(x) = ? \). Then we iteratively apply the bounded anchoring step, which changes a number of ?-classifications into \( \bar{S} \)-classifications. When no more ?-classifications can be changed, we are done.

Before considering bounded anchoring, we first give a definition of the set \( \bar{S} \) of size-change graphs and their composition along well-formed call sequences, and a definition of an equivalence class for parameters that are mutually dependent on each other.

Definition 6.2.1. (Summarizing path effects) \( \bar{S} = \{ G_{cs} \mid cs \text{ is well-formed} \} \)

Note that we now summarize effects, lumping together different call sequences that have the same size-change effect!

Definition 6.2.2. (Binding-time equivalence classes) We write \( x \equiv y \) if there exists \( G \in \bar{S} \) with an edge \( x \rightarrow y \) in \( G^s \) and a \( G' \in \bar{S} \) with an edge \( y \rightarrow x \) in \( G'^s \), and define the equivalence class \( [x] = \{ y \mid x \equiv y \} \).

Definition 6.2.3. (Bounded Anchoring) Let there be given a division \( \beta_q : \text{Varname} \rightarrow \{ S, ? \} \) and an equivalence class \( [y'] \) for which \( \beta_q(y) = ? \) for all \( y \in [y'] \). We define \( \beta_{q+1} \) by checking the following two conditions for all \( y \in [y'] \):

(1) For all $G' \in S$ which has an arc $x \rightarrow y$, $\beta_q(x) = S$ or $[x] = [y']$.

(2) For all $G : f \rightarrow f \in S$ where $G = G; G$ and $G'$ has an arc $y \rightarrow y'$, $G'$ has an arc $z \rightarrow z'$, and $\beta_q(z) = S$.

If both the conditions are true for all $y \in [y']$ then
$$\beta_{q+1}(x) = \begin{cases} S, & \text{if } x \in [y'] \\ \beta_q(x), & \text{otherwise} \end{cases}$$
otherwise, $\beta_{q+1} = \beta_q$.

In the second condition above, we say that $y$ is anchored in $z$ (for $G$).

**Theorem 6.2.4. (Correctness of Bounded Anchoring)** If $p$ quasiterminates for $\beta_q$, then $p$ quasiterminates for $\beta_{q+1}$.

**Proof.** Assume $p$ is quasiterminating for $\beta_q$, and suppose $p$ is not quasiterminating for $\beta_{q+1}$, i.e. for some $f^{(i)}$ with $\beta_{q+1}(f^{(i)}) = S$ and some (infinite state transition sequence) $\sigma$ we have $f^{(i)} \notin \text{bounded}(\sigma)$. Thus we can find an ascending sequence of values $u_1, u_2, \ldots$ such that $u_k = (v_k, r_k)$ (the $i$th component of the $k$th element of a subsequence of $v_0, r_0, \ldots$) where $\sigma = (f_0, v_0) \rightarrow^*(f_1, r_1) \rightarrow^* \cdots$ and $f = f_{u_k} = f_0 = \cdots = f_{u_k} = \cdots$. Obviously, as $p$ is quasiterminating for $\beta_q$ and $f^{(i)} \notin \text{bounded}(\sigma)$, we have $\beta_q(f^{(i)}) \not\subseteq S$, i.e. $f^{(i)} \in [y']$ in the bounded anchoring step from $\beta_q$ to $\beta_{q+1}$.

Choose a finite $M \in N$ such that $M > |\{v \in V \mid (x, V) \in \gamma(\sigma) \land \beta_q(x) = S\}|$, that is, greater than any value ever assigned to a bounded parameter; this is possible because $p$ is quasiterminating for $\beta_q$.

The rest of the proof is almost identical to that of the central theorem of the graph-based approach to termination detection presented by [Lee et al. 2001][Theorem 4];

Define a 2-set to be a 2-element set $\{t, t'\}$ of positive integers. Without loss of generality, $t < t'$. Let $m > M$ and a sequence of size change graphs $G_1, \ldots, G_m$ be given, and define for each $G \in S$

$$P_G = \{(t, t') \mid G = G_1; G_{t+1}; \ldots; G_{t'}\}$$

The set $\{P_G \mid G \in S\}$ is a family of classes: they are mutually disjoint, every 2-set $\{t, t', t, t' \leq m$ belongs to exactly one of them, and it is finite, since $S$ is finite.

By the Finite Ramsey’s Theorem [Ramsey 1930] given in Appendix A, we can compute an $m$ such that there exists a set $T$ of $M + 1$ indexes such that all 2-sets $\{t, t'\}$ with $t, t' \in T$ are in the same class $P_G$. Thus we have

$$G^2 = G_{t_1}; \ldots; G_{t_{L-1}} = (G_{t_1}; \ldots; G_{t_{L-1}}); (G_{t_2}; \ldots; G_{t_{L-1}}) = G^2; G^0$$

and

$$G^0 = G_{t_1}; \ldots; G_{t_{M+1}} = (G_{t_1}; \ldots; G_{t_{L-1}}); (G_{t_2}; \ldots; G_{t_{L-1}}) = G^0; G^0.$$
section $k$ into $G_k$, we get the sequence of $m$ size change graphs required above:

$$G'_1; \ldots; G'_{k-1}; \ldots; G'_{k_m-1} = G_1; \ldots; G_m$$

As each section $G'^{n}_{k}; \ldots; G'^{n}_{k+1-1}$ has a thread with at least one $\uparrow$ label, by Lemma 5.6.12 $G^\uparrow$ has an arc with an $\uparrow$ label, so by the second criterion of bounded anchoring, $G^\downarrow$ has an arc $z \xrightarrow{\downarrow} z$, where $\beta_q(z) = S$. Thus by Lemma 5.6.14 each section $G'^{n}_{k}; \ldots; G'^{n}_{k+1-1}$ has an $S$-thread with at least one $\downarrow$ label $z \xrightarrow{\downarrow} \ldots \xrightarrow{\downarrow} z$.

By Lemma 5.6.6 this implies that $\sigma$ has a thread $z \xrightarrow{\downarrow} \ldots \xrightarrow{\downarrow} z$ with at least $M$ $\downarrow$ labels. But this contradicts $\beta_q(z) = S$ because $M$ was chosen to be larger than any static value, and we conclude that $p$ is quasiterminating for $\beta_{q+1}$.

\[\Box\]

7. PARTIAL EVALUATION TERMINATION ANALYSIS

7.1 Syntax and semantics

Each expression of a program that is to be partially evaluated is annotated as static or dynamic, so we define the domains of annotated expressions, definitions and programs:

$$AProgram \ni p ::= d_1 \ldots d_n$$

$$ADef \ni d ::= f \ x_1^{n_1} \ldots x_n^{n_n} = e \!$$

$$AExpression \ni e ::= k^S \mid x_i \mid \text{lif} \ e_i^S \mid \text{if} \ \tau \ e_i^S \text{ then } e_2^r \text{ else } e_3^r \mid \text{b}^r \ e_i^S \ldots e_n^S \mid c : \ f^r \ e_i^S \ldots e_m^S \ f_{m+1} \ldots f_n^D \mid \tau \ni \{S,D\}$$

The lif construction is inserted around static expressions that are used in a dynamic context, so that the static value computed at specialization time is lifted into the residual program.

We now extend the meaning of $\beta$ to represent a binding-time division $\beta : AExpression \cup Varname \cup CallSite \rightarrow \{S,D,?\}$, which returns the binding time of its argument.

For simplicity, we consider only monovariant binding-time divisions, that is, each function parameter has the same binding time at all call sites, and wlog, we assume that all the static function parameters appear before the dynamic. The annotation $f^r$ in function calls indicates whether the call should be unfolded ($\tau = S$) at specialization time, or residualized ($\tau = D$), i.e. be a specialization point.

In the following we assume given the following domains:

$$v \in PEValue = Value \cup Expression$$

$$\varphi \in Memo = (FunName \times Value^*) \rightarrow FunName$$

$$\eta \in ResProg = \mathcal{P}(Def)$$

and a size relation $\leq \in Value \times Value$ which makes $Value$ well-founded.

\[38\] Traditionally, partial evaluation has employed monovariant binding-time divisions to avoid the risk of code explosion in the residual program. Christensen et al. [2000] have shown that polyvariant binding-time divisions can be viable and desirable in some cases.

\[\mathcal{PE} : AExpression \rightarrow PEValue^* \rightarrow Memo \rightarrow ResProg\]
\[\rightarrow (PEValue \times Memo \times ResProg) \cup \{\bot, \text{error}\}\]
\[\mathcal{PE} = \mathcal{PE}_{expr}[\lambda f.\{f_{\bot} \mapsto \lambda v_1 \ldots v_m. \mathcal{PE}_{expr}[e'_{\bot}](v_1, \ldots, v_m), \ldots,\]
\[fn_{\bot} \mapsto \lambda v_1 \ldots v_k. \mathcal{PE}_{expr}[e_{\bot}](\langle v_1, \ldots, v_k \rangle)\}]\]

\[\mathcal{PE}_{expr}[k^n]v_{\varphi_\eta_0} = \{\text{value } k, \varphi_0, \eta_0\}\]
\[\mathcal{PE}_{expr}[x_1]v_{\varphi_\eta_0} = \{v_1, \varphi_0, \eta_0\}\]
\[\mathcal{PE}_{expr}[\text{lift } e_2^n]v_{\varphi_\eta_0} = \{\text{lift } v'_1, \varphi_1, \eta_1\}\]
\[\text{where } (\varphi'_1, \eta'_1) = \mathcal{PE}_{expr}[e_1'](\varphi_1, \eta_1_{-1})\]
\[\mathcal{PE}_{expr}[\text{if } S e_1^n \text{ then } e_2 \text{ else } e_3]v_{\varphi_\eta_0} = \{\text{if } \varphi'_1 \text{ then } v'_2 \text{ else } v'_3, \varphi_0, \eta_0\}\]
\[\text{where } (\varphi'_1, \eta'_1) = \mathcal{PE}_{expr}[e_1'](\varphi_1, \eta_1_{-1})\]
\[\mathcal{PE}_{expr}[\text{if } D e_1^n \text{ then } e_2^n \text{ else } e_3^n]v_{\varphi_\eta_0} = \{\text{if } \varphi'_1 \text{ then } e_2^n, \varphi_0, \eta_0\}\]
\[\text{where } (\varphi'_1, \eta'_1) = \mathcal{PE}_{expr}[e_1'](\varphi_1, \eta_1_{-1})\]
\[\mathcal{PE}_{expr}[b^n e_1^n \ldots e_m^n]v_{\varphi_\eta_0} = \{\text{apply } b v'_1 \ldots v'_m, \varphi_0, \eta_0\}\]
\[\text{where } (\varphi'_1, \eta'_1) = \mathcal{PE}_{expr}[e_1'](\varphi_1, \eta_1_{-1})\]
\[\mathcal{PE}_{expr}[f^n S e_1^n \ldots e_m^n]v_{\varphi_\eta_0} = \{f^n(v'_1 \ldots v'_m, \varphi_0, \eta_0)\}\]
\[\text{where } (\varphi'_1, \eta'_1) = \mathcal{PE}_{expr}[e_1'](\varphi_1, \eta_1_{-1})\]

Fig. 7. Partial evaluation semantics. Use of ‘if’ are strict in the first argument, and all other functions on the right-hand side (lift, 1, 1, apply, etc.) are strict, returning \(\bot\) or error if any of their arguments are \(\bot\) or error.

In addition to the functions used in Figure 5, we now also make use of function \(\text{lift} : Value \rightarrow Constant\) which converts a constant value into the corresponding expression.

Partial evaluation of program \(P\) to static input \(\vec{e}\) is defined by \([\mathcal{PE} [f^n S e^n] \vec{e}] \{\}\), where operator \(\mathcal{PE}\) is defined in Figure 7.Pieces of residual program syntax are underlined. Note that if all parts of an expression \(e\) are annotated as static, and all function calls in \(e\) are calls to totally static functions, \(\mathcal{PE}\) performs normal, strict evaluation, so the lemmas from the preceding chapters apply to the static part of partial evaluation. The following lemma, easily proved by complete induction on the recursion depth, states that the \(\mathcal{PE}\) operator only ever adds entries to the memoization function \(\varphi\):

**Lemma 7.1.1.** If \(\{\bot, \text{error}\} \not\in [\mathcal{PE} [e] \vec{e}] \varphi_\eta = (\varphi', \varphi'', \eta')\) then \(\text{dom } \varphi \subseteq \text{dom } \varphi''\).

Definition 7.1.2. (Partial Evaluation State Transitions) Given a binding-time division \( \beta \),

1. A state transition \((f, \bar{v}) \rightarrow (g, \bar{u})\) is a pair of states connected by a call \( c : g \ e_1 \ldots e_n \) in the body \( e^f \) of \( f \), such that \( \bar{u} = (u_1, \ldots, u_m) \) and \( \mathcal{P}[e][\bar{v}][\varphi_{i-1}][\eta_{i-1}] = (u_i, \varphi_i, \eta_i) \) for some \((\varphi_i, \eta_i)\).

2. A state transition sequence is a (finite or infinite) sequence \( \sigma = (f_0, \bar{v}_0) \rightarrow \cdots \) where \((f_i, \bar{v}_i) \rightarrow (f_{i+1}, \bar{v}_{i+1})\) is a state transition for each \( i = 0, 1, \ldots \), and for any \( i \neq j \) with \((f_i, \bar{v}_i) = (f_j, \bar{v}_j)\), \( \beta(c_i) = S \) or \( \beta(c_j) = S \).

Note that memoization is modeled by disallowing transition sequences where the same specialization point is encountered twice for the same tuple of values, cf. Point \( \square \).

Definition 7.1.3. (S-threads) Given a binding-time division \( \beta \), an S-thread is a thread where \( \beta(x) = S \) for all nodes \( x \) in the thread.

7.2 Termination definitions

Definition 7.2.1. (Termination of Partial Evaluation) Given a binding-time division \( \beta \),

—We say that partial evaluation terminates for a function \( f \) wrt. static input \( \bar{v} = v_1 \ldots v_m \) if

\[ \mathcal{P}[f][x_1 \ldots x_m \ x_{m+1} \ldots x_n](v_1, \ldots, v_m, v_{m+1}, \ldots, v_n) \neq \bot. \]

—We say that partial evaluation terminates for program \( p = d_1 \ldots d_n \) iff partial evaluation terminates for \( tf \) for all \( \bar{v} \in \text{Value}^* \), where \( d_1 = (f_1 \ x_1 \ldots x_n = e^f) \).

As there are no iteration constructs in the language, and all base functions terminate, nontermination can only arise through recursive function calls. Furthermore, every dynamic call which is unfolded causes a new entry to be made in the memoization table:

Lemma 7.2.2. (Nontermination is caused by function calls) If \( \mathcal{P}[e][\bar{v}][\varphi_n] = \bot \), then there exists a call \( c : f \ e_1 \ldots e_n \) in \( e \) and \( \varphi_0, \ldots, \varphi_n \), \( \eta_0, \ldots, \eta_n \), \( \bar{v}, \varphi^0, \eta^0 \) with \( \text{dom } \varphi \subseteq \text{dom } \varphi^0 \) such that \( \mathcal{P}[f][e_1 \ldots e_n][\bar{v}][\varphi_n][\eta_n] = \mathcal{P}[e'][\bar{v}][\varphi'][\eta'] = \bot \), and \( \bot \neq \mathcal{P}[e][\bar{v}][\varphi_i][\eta_i] = (v_i, \varphi_i, \eta_i) \) for all \( i = 1, \ldots, n \). Furthermore, if \( \beta(c) = D \) then \((f, v_1 \ldots v_m) \not\in \text{dom } \varphi \) and \( (f, v_1 \ldots v_m) \not\in \text{dom } \varphi^0 \).

Proof. By structural induction on \( e \), considering Figure \( \square \) we note that \( e \not\equiv k \) and \( e \not\equiv \bar{x} \).

Case \( e \equiv \text{lift } e_1^f \). Directly by the induction hypothesis.

Case \( e \equiv \text{if } e_1 \text{ then } e_2 \text{ else } e_3 \). By Lemma \( \square \) we have \( \text{dom } \varphi = \text{dom } \varphi_0 \subseteq \text{dom } \varphi_1 \subseteq \text{dom } \varphi_2 \subseteq \text{dom } \varphi_3 \), so if \( \mathcal{P}[e_1][\bar{v}][\varphi_n] = \bot \) we simply apply the induction hypothesis to \( e_1 \); else if \( \mathcal{P}[e_2][\bar{v}][\varphi_1][\eta_1] = \bot \) we apply the induction hypothesis to \( e_2 \), else \( \mathcal{P}[e_3][\bar{v}][\varphi_2][\eta_2] = \bot \) and we apply the induction hypothesis to \( e_3 \).

Case \( e \equiv b e_1 \ldots e_n \). Analogous to the if case.

Case \( e \equiv f^S e_1 \ldots e_n \). The first part is analogous to the if case. Then, if \( \mathcal{P}[e][\bar{v}][\varphi_i][\eta_i] \neq \bot \) for all \( i = 1, \ldots, n \), this is the required call and \( \varphi^0 = \varphi_n \).
Case $e \equiv f^D e_1 \ldots e_n$. The first part is analogous to the if case. Then, if 
$P^E[e][\phi_{i-1}\eta_{i-1}] \neq \perp$ for all $i = 1, \ldots, n$, this is the required call. Further, we 
find that $(f, v_1, \ldots, v_m) \notin \text{dom } \phi_n \supseteq \text{dom } \varphi$, because otherwise $P^E[e][\phi \eta_{i-1}] \neq \perp$. 
This in turn implies that $P^E[f \; e_1 \ldots e_n][\psi \eta] = \phi \; f \; v_1 \ldots v_m \; x_1 \ldots x_{n-m} \; \psi'' \eta_m = \phi \; f \; v_1 \ldots v_m \; x_1 \ldots x_{n-m} \; \psi'' \eta_m$ with $(f, v_1, \ldots, v_m) \in \phi''$.

Lemma 7.2.3. If $P^E[f_0 \; x_1 \ldots x_m \; x_{m+1} \ldots x_n][\phi_0 \; \eta_0] = \perp$ then there exists an infinite state transition sequence $\sigma = (f_0, \bar{v}_0) \xrightarrow{c_1}\cdots$. 

Proof. Using Lemma [2], we find $\phi^1 = \varphi''$ and a call $c_1 : f_1 \; e_1 \ldots e_n$ in the body of $f_0$ for which 

$$P^E[f_1 \; e_1 \ldots e_n][\phi_{i-1}\eta_{i-1}] = \perp = P^E[e_1][\phi_{i-1}\eta_{i-1}]$$

and $\perp \neq P^E[e][\phi_{i-1}\eta_{i-1}] = (v_1, \varphi_i, \eta_i)$. Now letting $\bar{v}_1 = (v_1, \ldots, v_m)$, we find that $(f_0, \bar{v}_0) \xrightarrow{c_1}(f_1, \bar{v}_1)$ is a state transition, and $\phi^1 \subseteq \text{dom } \varphi$.

Continuing in this fashion with $e^1$ we find infinite sequences 

$$(f_0, \bar{v}_0) \xrightarrow{c_1}(f_1, \bar{v}_1) \xrightarrow{c_2}\cdots \xrightarrow{c_j}(f_j, \bar{v}_j) \xrightarrow{c_{j+1}}\cdots$$

$\phi^0 \subseteq \text{dom } \phi \subseteq \cdots \subseteq \text{dom } \phi^j \subseteq \cdots$

Now suppose for some $i < j$ that $(f_i, \bar{v}_i) = (f_j, \bar{v}_j)$ and $\beta(c_j) = D$. As $(f_j, \bar{v}_j) = (f_i, \bar{v}_i) \in \text{dom } \varphi_i \subseteq \text{dom } \varphi_j$, we cannot have $\beta(c_j) = D$, due to the way the transition $(f_{j-1}, \bar{v}_{j-1}) \xrightarrow{c_j}(f_j, \bar{v}_j)$ was constructed using Lemma [2]. Thus the sequence is a state transition sequence, cf. Definition [1.2]

Definition 7.2.4. (PEQ-termination) Program $p$ is said to be PEQ-terminating (partial evaluation quasi-terminating) for a binding-time division $\beta$ if for all parameters $x$ we have $\beta(x) = S \Rightarrow BV(x)$.

Lemma 7.2.5. (PEQ-termination implies termination of partial evaluation) Given a binding-time division $\beta$, if all function calls of program $p$ are marked $D$, and $p$ PEQ-terminates for $\beta$, partial evaluation of $p$ also terminates.

Proof. Assume $p$ is PEQ-terminating for a given binding-time division $\beta$. Let a function $f$ and static input $\bar{s} = s_1 \ldots s_m$ be given, and let $N$ be the upper bound on the size of poly, i.e. $N = \sum_s \; \text{poly}(s) \in \text{poly}_{m+1}$. Here, $(x_i, V_i) \in \psi(\bar{s})$; we note that $N$ is finite because $p$ is PEQ-terminating. Defining hypothesis

$H(n) = \text{for all } e_1 \eta$ and $\varphi$ for which $|\text{dom } \varphi| = N - n,$

and $|\text{dom } \varphi| \geq |\text{dom } \varphi'|$,

we prove the lemma by complete induction on $n$, noting that as all function calls are marked $D$, the first branch of function call interpretation is never used.

Case $n = 0$. This is proved by structural induction on $e$. The only case which is not immediately obvious is the recursive case to $P^E[e'][v_1 \ldots v_m]$$\psi'' \eta_m$ in the

function call interpretation, but this call will never be reached. This is due to the fact that when \( n = 0 \), \((f, v'_1, \ldots, v'_n) \in \text{dom } \varphi_n\).

\textbf{Case } n > 0. \textit{Again, this is proved by structural induction on } e. \textit{In this case we find that } |\text{dom } \varphi''| > |\text{dom } \varphi| \text{ in the recursive call to } \mathcal{PE}[\varphi']((v'_1, \ldots, v'_n))\varphi''\eta_n, \textit{so the induction hypothesis can be applied.} \qed

7.3 A termination-ensuring binding-time analysis
Recall that the binding-time division \( \beta : \text{Varname} \to \{S, D, ?\} \) classifies parameters as definitely static (\( S \)), definitely dynamic (\( D \)) or undecided (\( ? \)). A binding-time division that ensures termination is then constructed in the following way: First we classify as \( \beta_0(x) = D \) any parameter \( x \) that requires the values of the dynamic input to be known. Any remaining parameter \( y \) is classified \( \beta_0(y) = ? \). Then we iteratively apply the \textit{bounded anchoring step} (cf. Definition 6.2.3), which changes a number of ?-classifications into S-classifications. When no more ?-classifications can be changed by bounded anchoring, we change any remaining classification into \( D \).

7.4 Dynamic parameters and congruency
It is well-known that for partial evaluation defined in Figure 4 to work, the binding-time division \( \beta \) must be \textit{congruent}, that is, \( e_1 \) of any \( S \)-expressions and arguments \( e_1, \ldots, e_n \) of calls to basic functions \( b^S \) must be \( S \)-classified expressions, etc. The details of how to achieve congruency can be found elsewhere [Jones et al. 1993; Glenstrup 1999], here the important point to note is that whenever a parameter is classified \( D \), congruency may cause other parameters to be classified \( D \) too.

It is obvious from Definition 6.2.4 that if the final change of the binding-time division mentioned at the start of Section 6.3 only changes \( ? \) to \( D \), it will make no difference to the termination of partial evaluation of \( p \), and it is also obvious that partial evaluation of \( p \) terminates for \( \beta_0 \). In this case we conclude from Theorem 5.2.4 that partial evaluation will terminate for the final binding-time division.

If, however, the final change results in the need to change \( S \)-classified parameters into \( D \) due to congruency, resulting in a binding-time division \( \beta \), we must restart the entire process with a new binding time division

\[
\beta_0(x) = \begin{cases} 
D, & \text{if } \beta(x) = D \\
?, & \text{otherwise} 
\end{cases}
\]

As this new \( \beta_0 \) has strictly more parameters classified \( D \) than the original one, this process restart cannot go on forever, and we will end up with a congruent binding time division \( \beta \) for which partial evaluation terminates.

Note also that although the bounded anchoring process is restarted, we do not need to re-perform the costly computation of \( S \).

7.5 Specialization point insertion
Lemma 6.2.6 ensures termination of partial evaluation, but only if all function calls are residuated. In many cases it is desirable to perform some function calls at specialization time, e.g. the \texttt{1kxxx} functions in Figure 2.
To analyze the need for specialization points, conceptually we augment each function of the subject program \( p \) by adding a call depth parameter, called \( dp \). At every function call this parameter is incremented by 1 if the call is to another function in the same strongly-connected component of the program call graph, and reset to 0 otherwise. Thus \( dp \) reflects the call depth within the strongly-connected component. It is intuitively clear that if \( dp \) of all functions \( f \) are analyzed to be of bounded static variation, i.e. \( \beta(dp) = S \), specialization will terminate.

However, we can go further and compute minimized sets of specialization points which will guarantee that specialization will terminate. To this end, we extend the size-change graphs to include a set \( \Gamma \) of call sites, so that \( G'_c = (G'_c, \Gamma_1(c)) \) is the new size-change graph for call site \( c \). Composition of two size-change graphs \((G'_1, \Gamma_1), (G'_2, \Gamma_2)\) is as before, with the resulting call site set \( \Gamma \) being \( \Gamma_1 \cup \Gamma_2 \). We denote the set of call-site extended size-change graphs for program \( p \) by \( S' = \{ G'_c \mid \text{cs is well-formed} \} \), and define function \( \text{calls}(G'^, \Gamma) = \Gamma \).

To ensure termination we must now require for any idempotent \( G' \in S' \) in which \( dp \) is unanchored that there exists at least one specialization point in the set of calls \( \Gamma \) corresponding to \( G'^{} \):

**Theorem 7.5.1. (Specialization Point Insertion Correctness)** Given an augmented program \( p \) and a binding-time division \( \beta \), if \( p \) PEQ-terminates for \( \beta \), and for all \( G \in S' \) where \( G = G'; \) \( \beta(dp) \neq S \) there exists a \( c \in \text{calls}(G) \) for which \( \beta(c) = D \), then partial evaluation of \( p \) terminates.

**Proof.** Assume \( p \) PEQ-terminates for \( \beta \), but partial evaluation of \( p \) does not terminate, i.e. there exist function \( f \) and \( \bar{v} \in \text{Value}^* \) such that

\[
P\in[f \ x_1 \ldots x_m \ x_{m+1} \ldots x_n]\{(v_1, \ldots, v_m, x_1, \ldots, x_{n-m})\} = \top
\]

By Lemma 7.2.3 there exists an infinite state transition sequence \( \sigma = (f, \bar{v}) \xrightarrow{c_1} (f_1, \bar{v}_1) \xrightarrow{c_2} \ldots \xrightarrow{c_i} \ldots \). We let \( S'' = \{ G''_i \mid i = 1, \ldots \} \) where \( G''_i = (G'_c, \Gamma'_1, (c_1, \bar{v}_1)) \) with the same definition of composition as before. Note that \( S'' \) is finite because \( p \) PEQ-terminates, yielding only a finite number of different values \( \bar{v}_i \).

By a construction similar to that of the proof of Theorem 7.2.4 we can find a \( G''\in S'' \) with \( G'' = G'' \); \( G'' \) for which a part of \( M'(c) \) can be expressed as \((G'_1, \ldots, G'_{b-1}), (G'_b, \ldots, G'_{b-1})\), where \( G'_b; \ldots; G'_{b-1} = G'' \). Note that as \( \sigma \) is infinite, the set of values of \( dp \) is unbounded, so \( \beta(dp) \neq S \).

We now find that \( \beta(c) = S \) for all \( (c, \bar{v}) \in \text{calls}(G''\in S'') \); otherwise, as \( \xrightarrow{c}(f, \bar{v}) \) occurs twice, \( \sigma \) would violate the last requirement of a partial evaluation state transition sequence (cf. Definition 7.2.2).

8. **IMPLEMENTATION AND EXPERIMENTS**

A prototype of the bounded anchoring and specialization point analysis has been implemented in Scheme as an extension of the partial evaluator PEG [Thiemann 1999]. The implementation handles let expressions in the obvious way, and all higher-order and unknown functions (e.g., eval and apply) are conservatively size-approximated as returning values greater than all of their inputs.

8.1 Complexity

The analysis has been shown by Lee et al. [2001] to be intrinsically PSPACE complete, and the worst-case running time for PEQ-termination detection is exponential in the maximum arity of the functions of $p$. For instance, the size-change graphs of the program

\[
\begin{align*}
  f(x_1, y_1, \ldots, x_n, y_n) &= \text{if} \ldots \text{then} \\
  &\quad f(y_1, x_1, x_2, y_2, x_3, y_3, \ldots, x_n, y_n) \\
  \text{else} \quad f(x_n, y_n, x_1, x_2, y_2, \ldots, x_{n-1}, y_{n-1})
\end{align*}
\]

shown in Figure 8, force the analyzer to compute a set $S$ with $n2^n$ size change graphs: The dependency edges of each pair $(x_i, y_i)$ can be "rotated" up to $n$ times by composing a number of copies of $G_{\text{rotate}}$, and the edges of each of the $n$ pairs can be either "straight" or "swapped" by appropriate compositions of $G_{\text{swap}}$. This is confirmed by the implementation.

However, if the arity is assumed bounded, which is reasonable for typical programs, it can be shown that the implementation runs in worst-case cubic time in the size of $p$ [Glenstrup 1999].

Due to the additional gathering of sets of call sites, potentially yielding $O(2^n)$ different call site sets, insertion of specialization points requires worst-case exponential time in the size $n$ of $p$. We have reduced this problem by applying the following heuristic: We say that $G_1' \preceq G_2'$ when for every edge $x \rightarrow y \in G_1'$ there is an edge $x' \rightarrow y \in G_2'$ with $\delta \subseteq \delta'$, and for every edge $y \rightarrow x \in G_2'$ there is an edge $y \rightarrow x' \in G_1'$ with $\delta' \subseteq \delta$, and $\Gamma_1 \subseteq \Gamma_2$. In other words, $G_1'$ has "weaker" (or identical) anchors than $G_2'$. During the computing of $S'$ we then discard any $G_2' \in S'$ if there exists a $G_1' \in S'$ for which $G_1' \not\preceq G_2'$. Applying this heuristical optimization, the running times are reduced for typical programs.

8.2 Experiments

We have collected a suite of more than 50 small example programs, including several from the work of Lindenstrauss and Sagiv [1997]. The example programs are
all first order, so functions like fold and map use fixed functions for folding and mapping. Wherever it is vital for termination we have written natural numbers in unary notation, i.e. as list lengths, as the built-in integer type is not a well-founded domain. Furthermore, as we lose all size information for functions returning two values pointed to by a cons cell, we have slightly rewritten sorting functions. For instance, in mergesort merge (split xs) is changed into splitmerge xs [], [], where splitmerge splits xs into two lists using accumulating parameters and calls merge on them.

The programs and their analysis results are given in detail in Appendix C. In the majority of the examples all parameters are overconservatively generalized, the main exception being the list sorting functions. For these functions, the analyses are not sufficiently accurate for detecting that the length of the list does not change when it is sorted. In the following we will discuss just a couple of the example programs: An interpreter and a pattern matcher.

8.2.1 Simple first-order Scheme interpreter. This program, a Scheme implementation of the interpreter in Figure 2, is shown in Figure 9. As it stands it employs dynamic scoping, but removing the four lines labeled ‘DYNAMIC SCOPING’ changes it to employ static, lexical scoping. Function calls in the eval#exp function are numbered for easy reference. The results of the termination analysis and specialization-point insertion analysis are shown in Figure 10 for the interpreter using static scoping, and Figure 11 for the interpreter using dynamic scoping. The results confirm that the analysis correctly generalizes the names list when using dynamic scoping, but keeps it static under static, lexical scoping. Furthermore, the minimal number specialization points necessary for termination of specialization are computed. Note that as names can be unbounded for dynamic scoping, a specialization point is needed in the variable? function, which causes its return value to become dynamic. In this program it has no further effect, but in general such binding-time changes of return values must be propagated and the analyses reiterated.

8.2.2 Simple pattern matcher. The simple pattern matcher shown in Figure 12 takes a pattern and a string and returns a list of positions in the string where the pattern matches. For static pattern and dynamic string the analyzer correctly determines that n should be generalized, and that we must insert specialization points into the recursive calls to domatch, cf. Figure 13. However, if it is the string which is static, no parameters need to be generalized, and no specialization points are necessary.

9. RELATED WORK

The standard strategy for approaching termination in current implementations of partial evaluators is to insert memoization points at all dynamic conditionals [Bondorf and Danvy 1991]. This is based on the fact that if specialization then fails to terminate, there would also be a combination of inputs that would cause nontermination for normal evaluation. However, this strategy does not prevent nontermination when specializing an interpreter with dynamic scoping (cf. Section 8.2.1) where infinitely many residual functions would be generated. Neither

does the strategy prevent nontermination when specializing an interpreter to a
subject program containing an infinite loop with no conditionals.

Another approach is poor man's generalization [Holst 1988; Bondorf and Jørgensen 1993], in which all parameters that are not controlling the specialization
(i.e., are tested in an if construct) are generalized. This would lead to overly
conservative results for the interpreter, where both the list of names, ns, and the
program, pg, would be generalized, resulting in no specialization at all!

The concept of quasitermination was first considered by [Holst], which also
included a technique for generalizing parameters involved in an in-situ (i.e., from a
parameter to itself) increasing loop not anchored in an in-situ decreasing loop for
a static parameter of bounded variation. [Andersen and Holst 1996] presented an
analysis which includes the higher-order case. The first-order part of their analysis
is very similar to ours: they also employ a size dependency analysis prior to an
anchoring algorithm, and their transitive transition closure operation corresponds
to our computation of $S$.

The main differences are that we clearly separate the modalities by conceptually
using both $G^<$ and $G^>$, and state their safety conditions, which are substantially
different in nature. Our distinction between $\Delta$ and $\Lambda$ enables less conservative size
estimates for nested calls like

\begin{align*}
f x y d & \rightarrow \text{ if } d > 0 \text{ then } f (\max x y) y (d - 1) \text{ else } x \\
& \max u v & \rightarrow \text{ if } u > v \text{ then } u \text{ else } v
\end{align*}

In their analysis, assuming $d$ is dynamic, this would give rise to an increasing
transition $x \rightarrow x$ and thus a generalization of $x$, whereas we just record an equality
transition, leading to no generalization.

Furthermore we include an algorithm for inserting a set of necessary specialization
points, an essential ingredient in making specialization of quasi-terminating
programs terminate. This in turn requires that we handle cases where an ‘S’ parameter used as anchor becomes dynamic due to an inserted specialization point.

The present work is an extension of previous work [Glenstrup and Jones 1996; Glenstrup 1999], the main difference being the correctness proofs, and the size-change graph framework which allows less conservative annotations due to the condition that only increasing loops in idempotent size-change graphs need to be anchored.

Das’ [1998] work concerns mainly termination analysis for partial evaluation of real-world C programs, and is thus not directly comparable with our work. However, it is reasonable to assume that those techniques could be transferred to binding-time analyses for functional programs. The main differences between the essence of Das’ and our approach is that

—Das deals directly with control dependencies, whereas we emphasize the relationships between increasing and decreasing parameters. In fact, it turns out that to avoid too conservative binding-time divisions due to dynamic conditionals, he adds analyses similar to anchoring the call depth parameter to detect grounded loops and grounded flow cycles, which seems to indicate that this is the key property to consider in termination analysis for partial evaluation.

—Applying The Trick, for instance transforming a program with static parameter $s$ and dynamic parameter $d$ which is known to have a value between 1 and 10:

$$s = d \quad \text{into} \quad \textbf{while } (s \neq d) \quad s = s - 1; \quad s = s;$$

one has explicitly introduced a dynamic control dependency (from $s \neq d$) to an ‘S’ parameter ($ss$). This will cause Das’ control dependency approach to conservatively generalize the parameter, canceling the effect that was intended with The Trick. His solution is to require the user to explicitly annotate occurrences of The Trick in the code. Although this is a viable approach, we prefer good heuristics that can handle The Trick automatically in typical cases.

—Das only supplies a conditional termination guarantee: the resulting binding-time division may lead to static-infinite computations, whereas we detect parameters that are truly bounded, and supply a set of specialization points to avoid static-infinite computations. As partial evaluation is over-strict, possibly performing computations not intended by the programmer, we believe that a full termination guarantee should be given.

—Additionally, the part of Das’ work handling functional programs makes use of a weaker form of bounded anchoring, and will thus handle lexicographic ordering conservatively. In fact, his condition for detecting an unsafe, i.e. possibly unbounded, parameter $v$ is [Das 1998 Algorithm 3, p. 162]

\[ \text{If } v \text{ gets a value from an unbounded parameter } \]
\[ \text{or } (\text{there exists an increasing loop } v \rightarrow \cdots \rightarrow v \text{ and } \]
\[ \text{there exists no sibling parameter } w \text{ which decreases along all loops} \]
\[ w \rightarrow \cdots \rightarrow w) \]
\[ \text{then } v \text{ must be generalized to ensure termination} \]
This also prevents it from handling the interpreter example, because there exists an increasing loop eval₁₆ \rightarrow \cdots \rightarrow eval₁₆, but eval₁₆ cannot be used as an anchor in Das' condition, because it does not decrease along the loop for interpreting function calls (eval₁₆ is reset to some function body which is possibly larger).

— However, in Das’ approach, only one graph is used for both \( G^\uparrow \) and \( G^\downarrow \) because only tail-recursive programs are handled. Thus, both edges labeled \( \uparrow \) and \( \downarrow \) exist in the same graph, and context-free language reachability allows increasing edges \( \uparrow \) to “cancel out” decreasing edges \( \downarrow \) in cases where it is safe. This enables a more precise analysis e.g. of functions that return several values packaged with a cons cell which is later taken apart. There does not seem to be anything that in principle prevents an extension of this canceling effect to our analyses.

9.1 Pessimistic vs. optimistic binding-time analysis

One aspect that makes our approach stand out is that we start by assuming all parameters to be “unsafe,” i.e. marked ‘?’; and we only promote to ‘S’ when we have a guarantee (an anchor) that \( x \in bounded(\sigma) \). This can be termed a ‘safe’ or ‘pessimistic’ approach. Other approaches [Andersen and Holst 1996; Das and Reps 1996; Das 1998] are ‘optimistic’ in the sense that they start by marking all parameters ‘S’, and then re-classify as dynamic parameters which seem to be unbounded. We do not expect there to be any difference in power, i.e. that the safe approach generalizes parameters too conservatively\(^{13}\), but this has not been formally shown. One advantage of our safe approach is that one can “tail out” of the promotion process half way and still obtain a correct, albeit more conservative, result.

9.2 Proving termination by lexicographic ordering

Proving termination of programs has also been done by finding a tuple of parameters that can be shown always to decrease in some lexicographic ordering [Nielsen and Nielsen 1996], which must somehow be supplied by hand or by other analyses [Giesl 1995; Brainberger 1997]. The method presented in this paper includes detection of termination by lexicographic order, and this relies on the use of different anchors in different loops to allow less significant parameters in the lexicographic order to be reset to a greater value.

We can show that bounded anchoring is in fact strictly stronger than the lexicographic ordering approach. Consider the following

**Example 9.2.1.** (NO LEXICOGRAPHIC ORDERING)

\[
\begin{align*}
\text{f dp} \ (a_1, b_1) \ (a_2, b_2) \ (a_3, b_3) \ \cdots & \\
\text{if} \ \cdots \ \text{then} \ f^\uparrow (dp+1) \ (b_1-1, a_1-1) \ (a_2-1, b_2-1) \ (a_3-1, a_3-1) & \\
\text{else} \ f^\downarrow (dp+1) \ (b_1-1, a_1-1) \ (b_2-1, a_2-1) \ (a_3-1, b_3-1) &
\end{align*}
\]

In this example, we have tupled the parameters to highlight that parameter interactions only occur between \( a_i \) and \( b_i \).

\(^{13}\)Das [1998] Example 12] claims to have found an example which is treated differently by the two approaches, but our analysis does in fact give the same result as his.

It can be shown by bounded anchoring that specialization of \( f \) with all parameters static terminates (i.e., that \( dp \) is marked ‘\( S \)’):

1. All \( a \)'s and \( b \)'s are bounded (there are no increasing operations).
2. The only \( G \in S \) for which \( G; G = G \) is shown in Figure [4] (where all \( a \) and \( b \) have been left out of \( G \)) and it can clearly be seen that \( dp \) is anchored and thus bounded.

On the other hand, there exists no tuple of parameters from \( \{a_1, a_2, a_3, b_1, b_2, b_3\} \) such that they decrease for all loops \( f \rightarrow f \) in some lexicographic ordering: no single parameter is guaranteed never to increase, and thus no “most significant” parameter exists for a lexicographic ordering.

Although this example shows that bounded anchoring is in some theoretical sense stronger than techniques based on lexicographic ordering, it is doubtful whether this makes a difference for natural programs. What can be said is that the present approach is very operational and automatic: there is no need for a human to discover under what ordering termination should be proved.

9.3 Other work on size-change termination

The size-change termination principle was first used for detecting termination of normal evaluation [Lee et al. 2001] which only requires size-change graphs involving decreasing dependencies. The contribution of the present work is the addition of increasing dependencies necessary for termination analysis in partial evaluation, including the corresponding safety condition; expressing and proving correct the bounded anchoring principle in the size-change graph framework; and the use of analysis results for specialization-point insertion. In work made available to the authors recently [Lee 2002a; Lee 2002b], similar formulations and proofs are given. While Lee handles unfolding of static function calls (“local termination” of a reduction system) and dynamic function calls (“global termination” of a specializer state transition system) separately, the present work includes memoization directly in an operational definition of partial evaluation (cf. Figure 4). In Lee’s PhD Thesis [Lee 2002b], higher-order constructs are also handled.
10. CONCLUSION

The problem of termination of generated programs and program generators must be solved before fully automatic and reliable program generation for a broad range of applications becomes a reality. Achieving this goal is also necessary, if we hope ever to elevate software engineering from its current state (a highly-developed handwork) into a successful branch of engineering, capable of solving a wide range of new problems by systematic, well-automated and well-founded methods.

In this paper we have presented a binding-time and specialization-point insertion analysis for programs written in a first-order functional language. The analysis computes a binding-time division and a set of specialization points which we have proved ensure termination of the specialization phase.

Algorithms implementing the binding-time analysis obtain a worst-case complexity of $O(p^3)$ for programs of bounded arity, where $p$ is the program size. Computing a set of specialization points has exponential worst-case time, but can be reduced for typical programs using heuristical optimizations.

Experiments with a prototype implementation have shown that the analyses work well on several small example programs, and especially interpreters are handled well. Due to a rather crude size approximation, we are unable to prove termination of some of the example programs, mainly sorting algorithms that perform a lot of deconstructing and constructing operations.

This paper contributes towards making off-line partial evaluators automatic and useful tools, even for users who know little about specializer termination problems. But this is not all—the techniques presented here can also improve both the degree and speed of on-line specialization by annotating parameters that are guaranteed to be of bounded variation and thus do not need to be checked for homeomorphic embeddings, and do not need to be generalized. Another important contribution is, we hope, a better understanding of the problems occurring in the attempt to ensure termination of partial evaluation.

10.1 Directions for future work

10.1.1 Specialization-point insertion. The standard way of selecting specialization points is to choose all dynamic conditionals, unfolding all the original functions. This does not prevent static-infinite computations, nor does it prevent unbounded parameters during specialization. While our strategy guarantees termination, it would be interesting to compare it with the standard strategy for real-world programs.

As the algorithm for finding a small set of specialization points necessary for guaranteeing termination has exponential worst-case complexity, this problem should be addressed in depth in future research.

10.1.2 More precise size dependencies. The present algorithm is based on a rather crude approximation of the program values, using only $\uparrow$ and $\downarrow$ arrows, and is overly conservative in many cases, e.g. $\text{cdr} (\text{cons} x \ y)$ which could be considered as $\{\uparrow(y)\}$, but is approximated to $\{\uparrow(x), \uparrow(y)\}$. Das and Reps have addressed this problem, using context-free language reachability [Das 1996]. Das and Reps 1996], and an extension similar to this certainly seems necessary for treating any real-world examples. It could perhaps also be based on Hughes et al.'s [1996].

10.1.3 Other data domains. An obvious extension necessary for the analyses to be useful in practice is to handle integers and other data domains. This could be realized in a fairly straightforward manner by adding a domain analysis to find some bounds on the values that each parameter can be assigned during evaluation. Extending the termination analysis to cope with pointers or imperative constructs that can introduce cyclic data structures and aliasing would require some advanced analysis [Frodel and Le Métayer 1997] [Ghiya and Hendren 1996] to infer the “shapes” of the data structures (e.g., a list constructed using pointers), before they could be used as anchors.

10.1.4 General topics. We have described recent progress towards taming rather intricate problems in the context of partial evaluation. While the large lines are becoming much clearer, there is still much to do to bring these ideas to the level of practical, day-to-day usability. Therefore we conclude with a long list of goals and challenges.

Termination analysis.
—Develop a termination analysis for a realistic programming language, e.g., C, Java or C#.
—Develop termination-guaranteeing BTA for
  —a functional language (e.g., Scheme).
  —an imperative language (e.g., C).
  —more widely used programming languages (e.g., Java, C#).
—Develop a still stricter BTA to identify programs whose specialized versions will always terminate.
—Find ways to combine termination analysis with
  —abstract interpretation
  —other static analyses. For example, the size-change analysis depends critically on the fact that data is well-founded (e.g., natural numbers or lists), but the more common integer type is not well-founded.
One approach is to apply abstract interpretation to the type of integers to recognize non-negative parameters, and somehow combine this information with size-change analysis.

Partial evaluation.
—Perform efficient, reliable, predictable specialization of realistic programming languages, e.g., C, Java and C#.

Static program analyses.
—Devise an analysis for overlap detection, to discover when a function can be called repeatedly with the same arguments. Memoization can make such a program run faster, often yielding superlinear speedups, but should not be used indiscriminately due to time and space overhead.
—Devise a way automatically to estimate or bound a program’s running time, as a function of its input size or value.

\[ \varepsilon^+ = \varepsilon^+ \left( \lambda \phi : \{ f \} \mapsto \lambda \Delta_1 \ldots \Delta_m. \varepsilon^+ \phi \left[ e^H \right] \left( \Delta_1, \ldots, \Delta_m \right), \ldots, \\
\quad f_n \mapsto \lambda \Delta_1 \ldots \Delta_k . \varepsilon^+ \phi \left[ e^H \right] \left( \Delta_1, \ldots, \Delta_k \right) \right) \Delta^+_{id} \]

\[ \Delta^+_{id} = \{ \{ \mathbb{T}(x_1) \}, \ldots, \{ \mathbb{T}(x_n) \} \} \]

\[ \varepsilon^+ \phi \left[ k \right] \Delta = \{ \} \]

\[ \varepsilon^+ \phi \left[ \mathbf{e}_x \right] \Delta = \Delta_1 \]

\[ \varepsilon^+ \phi \left[ \mathbf{e}_1 \text{ if } e_1 \text{ then } e_2 \text{ else } e_3 \right] \Delta = \varepsilon^+ \phi \left[ \mathbf{e}_2 \right] \Delta \uplus \varepsilon^+ \phi \left[ \mathbf{e}_3 \right] \Delta \]

\[ \varepsilon^+ \phi \left[ \mathbf{e}_1 \ldots \mathbf{e}_n \right] \Delta = \varepsilon^+ \phi \left[ \varepsilon^+ \phi \left[ \mathbf{e}_1 \right] \Delta \right] \ldots \left( \varepsilon^+ \phi \left[ \mathbf{e}_n \right] \Delta \right) \]

where \( \Delta_1 \uplus \Delta_2 = \{ \mathbb{T}(f_z) \mid \mathbb{T}(f_z) \in \Delta_1 \uplus \mathbb{T}(f_z) \in \Delta_2 \} \uplus \{ \mathbb{T}(f_z) \mid \mathbb{T}(f_z) \in \Delta_1 \uplus \mathbb{T}(f_z) \in \Delta_2 \} \uplus \{ \mathbb{T}(f_z) \mid \mathbb{T}(f_z) \in \Delta_1 \cap \Delta_2 \} \)

and \( \varepsilon^+ \phi \text{ cons } \Delta_1 \Delta_2 = \{ \} \)

\[ \varepsilon^+ \phi \text{ cdr } \Delta_1 = \{ \mathbb{T}(f_z) \mid \delta(f_z) \in \Delta_1 \} \]

Fig. 15. Operator approximating decreasing size information for the value of an expression

APPENDIX

A. FINITE RAMSEY’S THEOREM

**Theorem A.1.** (Finite Ramsey’s Theorem) **There exists a computable function** \( R(e, r, k) \) **such that for all positive integers** \( e, r, k \) **and each finite set** \( M \) **the following holds:** if \( |M| \geq R(e, r, k) \), **and each** \( e \)-member subset of \( M \) **is marked by one of** \( r \) **colors, then there is a subset** \( H \) **of** \( M \) **such that** \( |H| = k \), **and all** \( e \)-member subsets of **\( H \)** are marked by the same color.

B. APPROXIMATION OPERATORS

Figures 12 and 13 show the approximation operators used in the implementation for the experiments. The \( \varepsilon^+ \) operator is a straightforward abstract interpretation of the program, while the \( \varepsilon^1 \) is more subtle because it must distinguish between bounded and unbounded size increases for infinitely many environments \( e \).

A call to the helper operator \( \varepsilon^1 \phi \left[ e^\uparrow \right] g F X \delta \Delta \) returns a triple \((\Delta', X', \delta')\) such that

\( \Delta' \) is the size dependency set for \( e \)

\( X' \) is the set of free variables encountered in if-tests during recursive descent and unfolding of \( e \) to any call to \( g \)

\( \delta' \) is ‘↑’ if there is an increasing operation (i.e., a cons) during recursive descent and unfolding of \( e \) to any call to \( g \), else it is ‘↓’

The arguments \( F, X, \) and \( \delta \) are accumulating parameters, where

\( F \) is the set of names of functions “on the call stack”

\( X \) is the set of free variables encountered in if-tests

\( \delta \) is ‘↑’ if an increasing operation (i.e., a cons) has been encountered, else it is ‘↓’

If an increasing operation is encountered between one call to a function \( f \) and a (possibly indirect) recursive call to itself, we say it has “recursive increase.” This is
\( \varepsilon^e[\varepsilon] = \Delta \)

where \( (\Delta, X, \delta) = \varepsilon^e(\text{fix } (\lambda \phi. \{ f1 \mapsto \lambda g FX \Delta_1 \ldots \Delta_m \cdot \varepsilon^e \phi [\varepsilon^e(f)] g F X (\Delta_1, \ldots, \Delta_m),

\quad f1 \mapsto \lambda g FX \Delta_1 \ldots \Delta_k \cdot \varepsilon^e \phi [\varepsilon^e(f)] g F X (\Delta_1, \ldots, \Delta_k))) \)

\[ \Delta^e_X = \left( \{ x_1 \}, \ldots, \{ x_n \} \right) \]

\( \varepsilon^e \phi [x] g F X \delta \Delta \) = \( (\{ \}, \{ \}, \{ \} \) \)

\( \varepsilon^e \phi [x_1] g F X \delta \Delta \) = \( (\Delta, \{ \}, \{ \} \) \)

\( \varepsilon^e \phi \left[ \text{if } e_1 \text{ then } e_2 \text{ else } e_3 \right] g F X \delta \Delta \) = \( (\Delta', X', \delta' \Delta') \) where \( (\Delta', X', \delta') = \varepsilon^e \phi [e_1] g F X \delta \Delta \)

\( \varepsilon^e \phi \left[ \text{cons } e_1 \ e_2 \right] g F X \delta \Delta \) = \( (\{ f2 \mid f2 \in \Delta_1 \cup \Delta_2 \}, X_1 \cup X_2, \delta_1 \cup \delta_2) \) where \( (\Delta_1, X_1, \delta_1) = \varepsilon^e \phi [e_1] g F X \delta \Delta \)

\( \varepsilon^e \phi \left[ \text{car } e_1 \right] g F X \delta \Delta \) = \( \varepsilon^e \phi [e_1] g F X \delta \Delta \)

\( \varepsilon^e \phi \left[ \text{if } e_1, \ldots, e_n \right] g F X \delta \Delta \) = \( (\Delta', X', X'' \cup X_1 \uplus \cdots \uplus X_n, \delta' \cup \delta_1 \cdots \cup \delta_n) \)

\( \varepsilon^e \phi [\text{analyze arguments}] g F X \delta \Delta \)

\( (\Delta', X', \delta') = \phi f g (F \cup \{ f \}) X \delta (\Delta_1, \ldots, \Delta_2) \) (analyze function call)

\( (X', \delta') = \text{if } f = g \text{ then } (X, \delta) \text{ else } (X'', \delta'') \) (return recursive increase info)

\( (\Delta', X', \delta') = \phi f \{ \} \uplus (\{ x_1 \}, \ldots, \{ x_n \}) \) (compute recursive increase information for \( f \))

\( \Delta' = \text{if } f \in F \uplus \{ \delta' \} \uplus \{ \text{free variables from if-tests} \} \) then \( \Delta'' \uplus \{ \text{free variables from if-tests} \} \) 

\( \text{recursive increase, then add } \Delta'' \)

\( \Delta_1 \uplus \Delta_2 = \text{if } \Delta_1 = \uplus \Delta_2 \) then \( \Delta' = \Delta'' \uplus \{ \text{free variables from if-tests} \} \)

Fig. 16. Operator for approximating increasing size information for the value of an expression. ‘•’ is a symbol distinct from all function names.

ture of the following functions which return the list length in a unary representation:

\[
\begin{align*}
\text{length1 } x s & = \text{ if } x s = \text{nil then nil else cons } 1 \text{ (length1 } (\text{cdr } x s)) \\
\text{length2 } x s \ l & = \text{ if } x s = \text{nil then } l \text{ else length2 } (\text{cdr } x s) \ (\text{cons } 1 \ l)
\end{align*}
\]

A safe approximation must include \( \uplus(xs) \) for these functions, but a naïve abstract interpretation would not detect this, because \( xs \) is only used in the if-tests.

\( \varepsilon^e \) of Figure 10 is safe because in the case of a function call \( f \ e_1 \ldots e_n \), all free variables of if-tests in recursive \( f \)-loops are conservatively added to the returned dependency set if \( f \) has recursive increase.

The remaining cases of \( \varepsilon^e \) are straightforward; note that the free variables of the if-test are added to the accumulating parameter \( X \) in the recursive calls for \( e_2 \) and \( e_3 \), and that the accumulating parameter \( \delta \) is changed to \( \uplus \) in the recursive call for \( e_1 \) and \( e_2 \) for the cons case.

\[ \begin{array}{l}
\bar{v}, \bar{\Delta} \vdash k \rightarrow k : \{\} \\
\bar{v}, \bar{\Delta} \vdash x_i \rightarrow v_i : \Delta_i \\
\bar{v}, \bar{\Delta} \vdash e \rightarrow \text{true} : \Delta_I' \\
\bar{v}, \bar{\Delta} \vdash \text{if } e_1 \text{ then } e_2 \text{ else } e_3 \rightarrow v'_2 : \Delta'_2 \\
\bar{v}, \bar{\Delta} \vdash \text{cons } e_1 \, e_2 \rightarrow (v'_1, v'_2) : \{\}
\end{array} \]

\[ \begin{array}{l}
\bar{v}, \bar{\Delta} \vdash e_1 \rightarrow (v'_1, v'_2) : \Delta' \\
\bar{v}, \bar{\Delta} \vdash \text{car } e_1 \rightarrow v'_1 : \Delta'_1 \\
\end{array} \]

Fig. 17. Inference system connecting evaluation and decreasing size approximation

B.1 Safety proofs

B.1.1 Safety of decreasing approximation. The inference system shown in Figure 17 is used to derive a judgment \( \bar{v}, \bar{\Delta} \vdash e \rightarrow v : \Delta \) which informally states that if evaluating \( e \) using \( \bar{v} \) for the free variables terminates, it yields \( v \), and also that under dependency environment \( \bar{\Delta} \), \( \Delta \) describes what \( e \) is decreasingly dependent on.

The following lemma states formally the connection to evaluation:

**Lemma B.1.1.** For all \( e, \bar{v}, \bar{\Delta} \), if \( \mathcal{E} [e] \bar{v} = v' \notin \{\text{error}, \perp\} \), then \( \bar{v}, \bar{\Delta} \vdash e \rightarrow v : \Delta \) is well-defined and \( v' = v \)

**Proof.** By fixpoint induction: let

\[ P(\phi) = \text{for all } e, \bar{v}, \bar{\Delta} \text{, if } \mathcal{E}_e \phi [e] \bar{v} = v' \notin \{\text{error}, \perp\}, \]  
then \( \bar{v}, \bar{\Delta} \vdash e \rightarrow v : \Delta \) is well-defined and \( v' = v \)

be the property we want to prove, and let

\[ F(\phi) = \{ f \mapsto \lambda x_1 \ldots x_m \cdot \mathcal{E}_e \phi [e/f] [x_1, \ldots, x_m], \ldots, \] 
\[ f_n \mapsto \lambda x_1 \ldots x_k \cdot \mathcal{E}_e \phi [e/f_n] [x_1, \ldots, x_k] \} \]

We now show

1: \( P(\perp) \). This is shown by structural induction over \( e \).

2: \( P(\phi) \Rightarrow P(F(\phi)) \). Assume \( P(\phi) \) and let \( e, \bar{v} \) be given such that \( \mathcal{E}_e (F(\phi)) [e] \bar{v} = v' \notin \{\text{error}, \perp\} \). If \( \mathcal{E}_e \phi [e] \bar{v} = v' \notin \{\text{error}, \perp\} \) then \( v' = v' \) because \( \phi \sqsubseteq F(\phi) \), and we are done.

Otherwise, \( \mathcal{E}_e \phi [e] \bar{v} = \perp \) and we perform structural induction over \( e \) using the hypothesis

\[ H(e) = \text{if } \mathcal{E}_e \phi [e] \bar{v} = \perp \text{ and } \mathcal{E}_e (F(\phi)) [e] \bar{v} = v' \notin \{\text{error}, \perp\}, \]  
then \( \bar{v}, \bar{\Delta} \vdash e \rightarrow v : \Delta \) is well-defined and \( v' = v \)

Case \( e \equiv k \) and \( e \equiv x_i \). Not applicable, because \( \mathcal{E}_e \phi [e] \bar{v} = \perp \)

Case \( e \equiv \text{if } e_1 \text{ then } e_2 \text{ else } e_3 \). Assume wlog. \( \mathcal{E}_e (F(\phi)) [e] \bar{v} = \text{true and } \mathcal{E}_e (F(\phi)) [e_2] \bar{v} = v' \). If \( \mathcal{E}_e [e_2] \bar{v} = v'' \notin \{\text{error}, \perp\} \) then \( v'' = v'' \) because
\(\phi \subseteq F \phi\), and we apply \(P(\phi)\). If, on the other hand, \(\mathcal{E}_e(\phi) [e_2] \bar{v} = v'' = \perp\), we apply the induction hypothesis \(H(e_2)\). Either way, we find that \(\bar{v}, \Delta \vdash e_2 \rightarrow v'_2 : \Delta_2\) is well-defined and \(v' = v'_2\). Applying the same reasoning to \(e_1\) and using the inference rule for \(if\), we find that \(\bar{v}, \Delta \vdash if e_1\) then \(e_2\) else \(e_3\) \(\rightarrow v'_2 : \Delta_2\) is well-defined and \(v' = v'_2\).

Case \(e \equiv\) \(\text{car}\ e_1\) and \(e \equiv\) \(\text{cdr}\ e_1\). Applying the same reasoning as in the \(if\) case we find that \(\bar{v}, \Delta \vdash e_1 \rightarrow (v'_1, v'_2) : \Delta\) is well-defined and \(\mathcal{E}_e(\phi) [e_1] \bar{v} = v' = (v'_1, v'_2)\) (\(v\) must be a cons cell because \(\mathcal{E}_e(\phi) [e] \bar{v} \neq \perp\)). The inference rule for \(\text{car}/\text{cdr}\) then shows this case.

Case \(e \equiv\) \(\text{cons}\ e_1\ e_2\). Analogous to the preceding case.

Case \(e \equiv f\ e_1 \ldots e_n\). By the same reasoning as the \(if\) case we find that \(\bar{v}, \Delta \vdash e_i \rightarrow v'_i : \Delta_i\) is well-defined and \(\mathcal{E}_e(\phi) [e_i] \bar{v} = v'_i \) for \(i = 1, \ldots, n\). We have \((\phi \ e_1 \ldots e_n = \mathcal{E}_e(\phi) [e_1]) (v'_1, \ldots, v'_n) = v' \not\in \{\text{error}, \perp\}\) which by applying \(P(\phi)\) implies that \((v'_1, \ldots, v'_n), \Delta_i \vdash e_i \rightarrow v'_i : \Delta_i\) is well-defined and \(v' = v'_i\).

3. \((\forall i : P(\phi_i)) \Rightarrow P(\bigcap_i \phi_i)\) for ascending chains \(\phi_1 \subseteq \phi_2 \subseteq \cdots\). Given \(\bar{v}\) and \(e\), assume \(\mathcal{E}_e(\bigcap_i \phi_i) [e] \bar{v} = v' \not\in \{\text{error}, \perp\}\). Then there must exist a \(\phi_i\) such that \(\mathcal{E}_e(\phi_i) [e] \bar{v} = v' \not\in \{\text{error}, \perp\}\), which by \(P(\phi_i)\) proves the desired property.

We extend the partial order \(\subseteq\) to labels, dependencies, dependency sets and dependency environments by

\[
\begin{align*}
\uparrow \subseteq \downarrow \\
\uparrow \subseteq \uparrow \\
\delta_1(x) \subseteq \delta_2(x) \Leftrightarrow \delta_1 \subseteq \delta_2 \\
\Delta_1 \subseteq \Delta_2 \Leftrightarrow \forall (\delta_1(x)) \in \Delta_1 : \exists \delta_2(x) \in \Delta_2 : \delta_1(x) \subseteq \delta_2(x) \\
\Delta_1 \subseteq \Delta_2 \Leftrightarrow \forall \forall : \exists \forall i : \exists \Delta_1 \subseteq \Delta_2
\end{align*}
\]

Definition B.1.2. Given \(\bar{u} \in \text{Value}^*\), we say that

\(\neg \Delta \ \bar{u}\)-describes \(v\) iff \((\forall j(x_j) \in \Delta \Rightarrow v < u_j) \\land \ (\exists j(x_j) \in \Delta \Rightarrow v \leq u_j)\)

\(\neg \Delta \ \bar{u}\)-describes \(\bar{v}\) iff \(\Delta_1 \ \bar{u}\)-describes \(v_i\) for all \(i\).

Corollary B.1.3. If \(\Delta' \subseteq \Delta\) and \(\Delta \ \bar{u}\)-describes \(v\) then \(\Delta'\) also \(\bar{u}\)-describes \(v\). Further, if \(\Delta \ \bar{u}\)-describes \(v\), then \(\Delta \bigcap \Delta''\) (cf. Figure 13) also \(\bar{u}\)-describes \(v\) for any \(\Delta''\).

Now that we have made the connection to normal evaluation, the following key lemma shows the required safety relation:

Lemma B.1.4. Let \(\bar{u}\) be given. Now for all \(e, \bar{v}, \Delta\), if \(\mathcal{E}_e [e] \bar{v}\) terminates without errors and \(\Delta \ \bar{u}\)-describes \(\bar{v}\), then \(\bar{v}, \Delta \vdash e \rightarrow v : \Delta\) is well-defined, \(\forall \Delta' \subseteq \Delta : \mathcal{E}_e [e] \bar{v} \not\in \{\text{error}, \perp\}\) and \(\Delta \ \bar{u}\)-describes \(v\).

Proof. Let \(\bar{u}, \bar{v}, \Delta, \Delta'\) be given such that \(\Delta \ \bar{u}\)-describes \(\bar{v}\), \(\Delta' \subseteq \Delta\) and assume \(\mathcal{E}_e [e] \bar{v} \not\in \{\text{error}, \perp\}\). By Lemma B.1.1 we know that \(\bar{v}, \Delta \vdash e \rightarrow v : \Delta\) is well-defined, so we proceed by induction over the height of the inference tree, considering the syntax of \(e\):

Case \(e \equiv k\). Trivial.

Case \(e \equiv x_i\). Immediate by Corollary B.1.3.

Case $e \equiv \text{if } e_1 \text{ then } e_2 \text{ else } e_3$. Straightforward by induction and Corollary [B.1.3]

Case $e \equiv \text{cons } e_1. e_2$. Trivial, because $\xi_{\text{b}} e_1. e_2 \equiv \emptyset$.

Case $e \equiv \text{car } e_1$ and $e \equiv \text{cdr } e_1$. By induction we know that $\Delta_1 \equiv \xi_{\text{b}} \phi \llbracket e_1 \rrbracket \Delta' \subseteq \Delta$ and that $\Delta' \models v$-describes $(v_1, v_2)$. Now if $\downarrow(x) \in \xi_{\text{b}} \phi \llbracket e \rrbracket \Delta = \{ \downarrow(x) \mid \delta(x) \in \Delta \}$, then $\delta(x) \in \xi_{\text{b}} \phi \llbracket e_1 \rrbracket \Delta \subseteq \Delta'$, so $\delta'(x) \in \Delta'$, which, by the inference rule implies that $\downarrow(x) \in \downarrow \Delta' = \Delta$, proving that $\xi_{\text{b}} \phi \llbracket e \rrbracket \Delta \subseteq \Delta$. Further, if $\downarrow(x_i) \in \Delta = \downarrow \Delta$ then $\delta(x_i) \in \Delta'$, that is, $(v_1', v_2') \leq u_i$, which implies that $v_1' < u_i$ and $v_2' < u_i$, so $\Delta$ does indeed $v$-describe $v$. \hfill $\Box$

Case $e \equiv f e_1 \ldots e_n$. By induction we know that $\Delta'' = \xi_{\text{b}} \phi \llbracket e \rrbracket \Delta' \subseteq \Delta$ and $\xi_{\text{b}} \phi \llbracket e \rrbracket \Delta' \subseteq \Delta' \models v = v'$ for $\Delta = (\Delta', \ldots, \Delta''')$, so $\xi_{\text{b}} \phi \llbracket e \rrbracket \Delta' = \xi_{\text{b}} \phi \llbracket e \rrbracket \Delta' = \Delta$. Further, by induction we know that $\Delta = \Delta' \models v = v'$.\hfill $\Box$

By letting $\sigma = v'$ and $\Delta' = \Delta$ in Lemma [B.1.3] we find that $\xi_{\text{b}} \llbracket e \rrbracket \Delta = \Delta'$ where $\Delta' \models v$ because $\Delta' \subseteq \Delta$ which implies

**Corollary B.1.5.** $\xi_{\text{b}} e$ is safe.

### 1.1.2 Safety of increasing approximation

The inference system shown in Figure [18] is used to derive a judgment $\overline{\alpha}, \Delta \vdash e \rightarrow v : \Delta$ which formally states that if evaluating $e$ using $\overline{\alpha}$ for the free variables terminates, it yields $v$, and also that under dependency environment $\overline{\alpha}, \Delta$ describes what $e$ is increasingly dependent on. The inference system is similar to that of Figure [17] and as only the approximations are different, Lemma [B.1.1] applies.

**Definition B.1.6.** Given $\tilde{U} = \overline{u_1}, \overline{u_2}, \ldots \in (\text{Value}^n)^\omega$, $\tilde{V} = \overline{v_1}, \overline{v_2}, \ldots \in (\text{Value}^m)^\omega$ and $W = w_1, w_2, \ldots \in \text{Value}^\omega$, we say that

- $\tilde{U}$ describes $W$ iff for all $X \subseteq \{1, \ldots, n\}$
  \[\sum_{i \in X} |\{u_j\}| = \sum_{i \in X} |\{j \mid w_j > u_j\}| = \infty \Rightarrow \exists \delta \in X : \uparrow(x_i) \in \Delta \text{ and } \sum_{i \in X} |\{u_j\}| = |\{w_j\}| = \infty \Rightarrow \exists \delta \in X : \delta(x_i) \in \Delta.\]

- $\tilde{V}$ describes $\tilde{U}$ iff $\tilde{V} = v_1, v_2, \ldots \text{ for all } i \in \{1, \ldots, m\}.$

**Corollary B.1.7.** If $\Delta' \supseteq \Delta$ and $\tilde{U}$ describes $W$ then $\Delta'$ also $\tilde{U}$ describes $W$. Further, if $\Delta \models \tilde{U}$ describes $W$, then $\Delta \uparrow^\omega \Delta''$ (cf. Figure [16]) also $\tilde{U}$ describes $W$ for any $\Delta''$. 

**Lemma B.1.8**. Let \( \bar{\Delta} \) be given. Now for all \( e, \bar{\Delta}, \bar{\Delta}_i \), if for all \( j \in \mathcal{I} \) \( \bar{\Delta}_j \) terminates without errors and \( \bar{\Delta} \) \( \bar{\Delta}_i \)-describes \( \bar{\Delta}_j \), then \( \bar{\Delta}_j \Delta \vdash e \iff w_j : \Delta \) is well-defined, \( \forall \bar{\Delta}' \bar{\Delta} \vdash \bar{\Delta}_i \Delta e \Rightarrow \check{\bar{\Delta}}' \bar{\Delta} \equiv \bar{\Delta}_i \), and \( \Delta \bar{\Delta}_i \)-describes \( \bar{\Delta} \).

**Proof.** Let \( h \) denote the maximum height of the inference trees and consider two cases:

**Case** \( h < \infty \). We proceed by induction over the maximum height of the inference trees for \( j = 1, 2, \ldots \). In each case \( \check{\bar{\Delta}}_i \Delta e \Rightarrow \bar{\Delta} \) is obvious, so we show just that \( \Delta \bar{\Delta}_i \)-describes \( \bar{\Delta} \).

**Base case** \( e \equiv k \). We find \( w_j = k \), so \( |\{ j \mid w_j > u_{j,i} \}| < \infty \) and \( |\{ w_j \}| < \infty \), which makes the implications vacuously true.

**Base case** \( e \equiv x_i \). We find \( w_j = v_{j,i} \), and by the premise we see that \( \check{\bar{\Delta}}_i \Delta e \Rightarrow \bar{\Delta}_i \bar{\Delta}_i \)-describes \( \bar{\Delta}_i \).

**Inductive case** \( e \equiv k \). Then \( e_2 \) else \( e_3 \). For given \( X \), suppose wlog. that \( \bar{\Delta}_j \Delta \vdash e_1 \Rightarrow \bar{\Delta}_i \Delta \vdash e_2 \). Similar reasoning applies if \( \bar{\Delta}_j \Delta \vdash e_3 \).

**Inductive case** \( e \equiv \text{cons} e_1 e_2 \). For given \( X \), if \( \sum_{i \in X} |\{ j \mid w_{j,i} > u_{j,i} \}| = \infty \) and \( \sum_{i \in X} |\{ j \mid w_{j,i} > u_{j,i} \}| = \infty \) or \( |\{ w_j \}| = \infty \), then we can assume wlog. that \( |\{ w_{j,i} \}| = \infty \), where \( w_{j,i}', w_{j,i}'' = w_j \), and apply the induction hypothesis to \( e_1 \). We then find \( \exists i \in X : \bar{\Delta}_i \Delta \vdash e \) as required.

**Inductive case** \( e \equiv \text{car} e_1 \) and \( e \equiv \text{cdr} e_1 \). For given \( X \), if \( \sum_{i \in X} |\{ j \mid w_{j,i} > u_{j,i} \}| = \infty \) and \( \sum_{i \in X} |\{ j \mid w_{j,i} > u_{j,i} \}| = \infty \) or \( |\{ w_j \}| = \infty \), then the same is the case for \( w_j, w_j' \) and \( w_j, w_j \), so the induction hypothesis can be applied.

**Inductive case** \( e \equiv f e_1 \ldots e_n \). Applying the induction hypothesis to \( e_1, \ldots, e_n \), we find that \( \Delta_i \Delta \vdash f e_1 \ldots e_n \) \( \bar{\Delta}_i \Delta \vdash e_1 \ldots e_n \), and \( \Delta'_i = \check{\bar{\Delta}}_i \Delta e \Rightarrow \bar{\Delta}_i \Delta \vdash e_1 \ldots e_n \), so we can apply the induction hypothesis to \( e', f \), finding that \( \check{\bar{\Delta}}_i \Delta e \Rightarrow \bar{\Delta}_i \Delta e \Rightarrow \bar{\Delta}_i \Delta \vdash e_1 \ldots e_n \) \( \check{\bar{\Delta}}_i \Delta \vdash \bar{\Delta}_i \Delta \)-describes \( \bar{\Delta} \).

**Case** \( h = \infty \). For given \( X \), if we can find an infinite subsequence \( j_1, j_2, \ldots \) for which \( \sum_{i \in X} |\{ j \mid w_{j,i} > u_{j,i} \}| = \sum_{i \in X} |\{ j \mid w_{j,i} > u_{j,i} \}| = \infty \) or \( \sum_{i \in X} |\{ j \mid w_{j,i} > u_{j,i} \}| = \infty \) and the maximum height of the inference trees for this subsequence is \( h_i < \infty \), we proceed as for \( h < \infty \).

Otherwise, the number of function call inference steps occurring in an inference tree must be unbounded, and thus there must be a function \( f \) which loops an unbounded number of times. Further, as \( |\{ w_j \}| = \infty \), this loop must involve a recursive increase, and as each inference tree is of finite height, the loop must include at least one \( \text{if-expression} \) in which a free variable of the condition depends on \( x_i \) for some \( i \in X \), so \( \bar{\Delta}_i \Delta \vdash \check{\bar{\Delta}}_i \Delta \).

Termination Analysis and Specialization-Point Insertion in Partial Evaluation

Received ???-Month ???; ???-Month ???; accepted ???-Month ????

C. DETAILED ANALYSIS RESULTS

An overview of the results of the binding-time analysis, given binding-time patterns for each goal function, are shown in Tables B.11. By manually looking at each program, we have listed the optimal analysis result, i.e. the fewest generalisations and specialisation point insertions necessary to guarantee termination of specialisation, and whether the prototype is able to achieve this or is more conservative.

Even though the sorting functions have been rewritten as previously described, the analyser is not able to detect that they terminate. This is because during the reordering of the list, our rather crude size approximations lose track of the list sizes. One could patch on this problem by passing around a measure of the list lengths (and decreasing them whenever the lists got shorter), but that would not be a natural way to write the sorting functions.

The function for rewriting an expression with an associative operator, assoc, cannot be proven by the analyser to terminate. This should come as no surprise, as it requires an advanced size measure not only keeping track of the number of cons nodes but also the structure of the syntax tree.

The example program nestimeq! shows one shortcoming of the size approximation function $\mathcal{E}^5$; for the function

\[
\text{immatcopy } x \text{ if } x = [] \text{ then } [] \text{ else cons (car } x) \text{ (immatcopy (cdr } x))
\]

our size approximation cannot detect that the size of the return value of a call \text{immatcopy } x is the same as the size of \( x \), resulting in conservative generalisation. Similar problems occur with a \text{revapp} call in \text{permute}, and a \text{reverse} call in \text{shuffle}.

The remaining examples are handled without resulting in overconservative results, notably including several interpreters.

The programs and results are given in detail in the following sections. The binding times are given by
App-2  ·  A. Glenstrup and N. Jones

  (if (pair? p)
      (if (= (equal? 'and (car p))
              (and (disj? (cadr p)) (conj? (caddr p)))
       (bool? p))
       (bool? p)))
(define (bool? p) (or (equal? 'f p) (equal? 't p)))

Parameter binding times:
  bool?: pB:
  conj?: pB:
  disj?: pB:
  disj conj?: pB:

Specialisation points:
  None.

C.3.12 duplicate

;;; Compute a list where each element is duplicated
(define (goal x) (duplicate x))
(define (duplicate x)
  (if (= (equal? xs '())
          (cons (car xs) (cons (car xs) (duplicate (cdr xs))))))

Parameter binding times:
  duplicate: xB:
  goal: xB:

Specialisation points:
  None.

C.3.13 equal

(define (equal x) (equal x))
(define (equal x) (if (= (equal? x '()) 42 (equal x)))

Parameter binding times:
  equal: x : B
  goal: x : B
Specialisation points:
  Call 1 is equal to equal

C.3.14 even_odd

;;; Predicate: is x, unary represented as '(a s s ... s), even/odd?
(define (even_odd x) (even? x))
(define (even? x) (if (null? x) #t (odd? (cdr x))))
(define (odd? x) (if (pair? x) (even? (cdr x)) #f))

Parameter binding times:
  odd?: x : B
even?: x : B
even_odd: x : B
Specialisation points:
  None.

C.3.15 exponential

;;; These functions produce n^2 = size-change graphs
(define (f1 x y)
  (if x
      (f1 y x)
      (f1 x y))))

(define (f2 x y)
  (if x

      (f4 y y x y x y y y y y)));

(define (f5 x y)
  (if x
      (f5 y x y y y y y y y y y y y y)
      (f5 y y x y x y y y y y y y y y y y)));

Parameter binding times:
  f5: x : B y : B
eq : B
eq : B
f4: x : B y : B
eq : B
eq : B
f3: x : B y : B
eq : B
eq : B
f2: x : B y : B
eq : B
eq : B
f1: x : B y : B
Specialisation points:
  Call 2 in f1 to f1
  Call 1 in f3 to f3
  Call 1 in f4 to f4
  Call 1 in f2 to f2
  Call 1 in f5 to f5
  Call 1 in f3 to f3
  Call 2 in f3 to f2
  Call 1 in f2 to f2
  Call 2 in f5 to f2
  Call 2 in f4 to f4
  Call 2 in f5 to f5

C.3.16 fold

;;; The fold operators, using a fixed operator, op
(define (fold op x) (cons (fold1 op x) (cons (foldr op x) '())))
(define (fold1 op x)
  (if (pair? x)
      (fold1 (op a (car x)) (cdr x)) a))

(define (foldr op x)
  (if (pair? x)
      (op (car x) (foldr op (cdr x))) a))

(define (op z1 z2) (+ z1 z2))

Parameter binding times:
op: z1 : S z2 : D
fold: a : D mx : B
fold: a : D mx : B
Specialisation points:
None.

Parameter binding times:
op: z1 : S z2 : D
fold: a : B mx : D
fold: a : B mx : D
Specialisation points:
Call 2 in fold to fold
Call 1 in fold to fold

C.3.17 game

; The game function from Hansur Darm's PhD Thesis (p. 137)
(define (goal p1 p2 moves) (game p1 p2 moves))
(define (game p1 p2 moves)
  (if (equal? moves '())
    (cons p1 p2)

      (if (equal? (car moves) 'capture)
        (game (cons (car p2) p1) (cdr p2) (cdr moves))
        'error))))

Parameter binding times:
game: p1 : S p2 : B moves : B
goal: p1 : B p2 : B moves : B
Specialisation points:
None.

C.3.18 increase

(define (goal x) (increase x))
(define (increase x) (if (equal? x '()) 42 (increase (cons 1 x)))))

Parameter binding times:
increase: x : S
goal: x : B
Specialisation points:
Call 1 in increase to increase

C.3.19 intlookup

; The function call case of an interpreter
; Function number represented as list length
(define (run e p) (intlookup e p))
(define (intlookup e p) (intlookup (lookup e) p))
(define (lookup fun p)
  (if (equal? fun '()) (car p) (lookup (cdr fun) (cdr p)))))

Parameter binding times:
lookup: fun : B p : B
intlookup: e : D p : B
run: e : D p : B
Specialisation points:
Call 1 in intlookup to intlookup

C.3.20 letexp

; Testing the let construction
(define (goal x y) (letexp x y))
(define (letexp x y) (let* ((z (cons 1 x)) (letexp x y)))

Parameter binding times:
letexp: x : S y : B
goal: x : B y : B
Specialisation points:
Call 1 in letexp to letexp
C.3.21 list
;; The predicate for checking whether the argument is a list
(\(define\ (list?\ x)\ (list?\ x)\))
(\(define\ (list?\ xs)\ (if\ (pair?\ xs)\ (list?\ (cdr\ xs))\ (null?\ xs))))

Parameter binding times:
list?:\ \(x: B\)
goal: \(x: B\)
Specialisation points: none.

C.3.22 lte
;; Less than or equal
(\(define\ (goal\ x\ y)\ (lte\ x\ y)\ (even?\ x)))
(\(define\ (lte?\ x\ y)\ (if\ (null?\ x)\ \(\lambda\)\ (if\ (and\ (pair?\ x)\ (pair?\ y))\ (lte?\ (cdr\ x)\ (cdr\ y))\ \$))\))
(\(define\ (even?\ x)\ (if\ (null?\ x)\ \$\ (if\ (null?\ (cdr\ x))\ (even?\ (cdr\ (cdr\ x))))\))

Parameter binding times:
even?:\ \(x: B\)
lte?:\ \(x: B\ \ y: D\)
goal: \(x: B\ \ y: D\)
Specialisation points: none.

C.3.23 map
;; The map function with fixed function f
(\(define\ (goal\ xs)\ (map\ xs))\)
(\(define\ (map\ xs)\ (if\ (equal?\ xs\ '())\ \(\lambda\)\ (cons\ (f\ (car\ xs))\ (map\ (cdr\ xs))))\))
(\(define\ (f\ x)\ (+\ x\ x))\)

Parameter binding times:
f: \(x: B\)
map: \(xs: B\)
goal: \(xs: B\)
Specialisation points: none.

C.3.24 member
;; The member function
(\(define\ (goal\ x\ xs)\ (member?\ x\ xs))\)
(\(define\ (member?\ x\ xs)\ (if\ (equal?\ xs\ '())\ \(\lambda\)\ (if\ (equal?\ x\ (car\ xs))\ \$\ (member?\ x\ (cdr\ xs))))\))

Parameter binding times:
member?: \(x: B\ \ xs: B\)
goal: \(x: B\ \ xs: B\)
Specialisation points: none.
Parameter binding times:
member?: x : B xs : D
    goal: x : B xs : B
Specialisation points:
    Call 1 if member? to member?

C.3.25 merge lists

;;; Merge two lists
(defun (merge goal xs ys)
  (if (equal? xs nil)
      ys
    (if (equal? ys nil)
      xs
    (cons (car xs) (merge (cdr xs) (merge (car xs) (car ys))))))

Parameter binding times:
merge: xs : B ys : D
goal: xs : B ys : D
Specialisation points:
    Call 2 in merge to merge

C.3.26 mul

;;; Unary multiplication and addition, e.g. (mul '(s s s) '(s s s s))
(defun (mul goal x y)
  (if (equal? x nil)
      y
    (mul (cdr x) y (add (car x) y))))

Parameter binding times:
add: x : D y : D
mul: x : B y : B
    goal: x : B y : B
goal: x : B y : B
Specialisation points:
    Call 1 in add to add

C.3.27 sawererev

;;; Sawai reverse function
(defun (sawererev goal x)
  (if (equal? x nil)
      nil
    (sawererev (cdr x) (sawererev (car x))))

(defun (app xs y)
  (if (equal? xs nil)
      (cons (car y) (sawererev (car y)))
    (app (sawererev (cdr y)) (cons (car y) (sawererev (car y))))))

Parameter binding times:
app: xs : B y : B
sawererev: xs : B
goal: xs : B
Specialisation points:
none.

C.3.28 nestdec

;;; Parameter decrease by nested call in recursion
(defun (nestdec goal x)
  (if (equal? x nil)
      nil
    (nestdec (dec x) (nestdec (dec x))))

(defun (dec goal x)
  (if (equal? x nil)
      nil
    (nestdec (cdr x) (dec (cdr x)))))

Parameter binding times:
dec: x : B
nestdec: x : B
goal: x : B
Specialisation points:
none.

C.3.29  \textit{nesteql}

; Parameter equality by nested call in recursion
\begin{verbatim}
(define (nesteql x) (if (equal? x '()) T (nesteql (eql x))))
\end{verbatim}
\begin{itemize}
\item Parameter binding times:
  \begin{itemize}
  \item \texttt{eql}: \texttt{X : B}
  \item \texttt{nesteql}: \texttt{X : B}
\end{itemize}
\item Specialisation points:
  \begin{itemize}
  \item Call 1 in \texttt{eql} to \texttt{eql}
  \item Call 1 in \texttt{nesteql} to \texttt{nesteql}
\end{itemize}
\end{itemize}

C.3.30  \textit{nestimeq}

; Using an inmaterial "copy" as recursive argument
\begin{verbatim}
(define (nestimeq x) (if (equal? x '()) T (nestimeq (imatchcopy x))))
\end{verbatim}
\begin{itemize}
\item Parameter binding times:
  \begin{itemize}
  \item \texttt{imatchcopy}: \texttt{X : S}
  \item \texttt{nestimeq}: \texttt{X : S}
  \item \texttt{goal}: \texttt{X : B}
\end{itemize}
\item Specialisation points:
  \begin{itemize}
  \item Call 1 in \texttt{imatchcopy} to \texttt{imatchcopy}
  \item Call 1 in \texttt{nestimeq} to \texttt{nestimeq}
\end{itemize}
\end{itemize}

C.3.31  \textit{nestinc}

; Parameter increase by nested call in recursion
\begin{verbatim}
(define (nestinc x) (if (equal? x '()) T (nestinc (inc x))))
\end{verbatim}
\begin{itemize}
\item Parameter binding times:
  \begin{itemize}
  \item \texttt{inc}: \texttt{X : S}
  \item \texttt{nestinc}: \texttt{X : S}
  \item \texttt{goal}: \texttt{X : B}
\end{itemize}
\item Specialisation points:
  \begin{itemize}
  \item Call 1 in \texttt{inc} to \texttt{inc}
  \item Call 1 in \texttt{nestinc} to \texttt{nestinc}
\end{itemize}
\end{itemize}

C.3.32  \textit{solexord}

; Example not termination-provable by simple lexicographical ordering
\begin{verbatim}
(define (goal a1 b1 a2 b2 a3 b3) (sollexord a1 b1 a2 b2 a3 b3))
\end{verbatim}

    T
    (sollexord
     (cdr b1) (cdr a2) (cdr b2) (cdr a3) (cdr b3)))
\end{verbatim}
\begin{itemize}
\item Parameter binding times:
  \begin{itemize}
  \item \texttt{solexord}: \texttt{a1 : B b1 : B a2 : B b2 : B a3 : B b3 : B}
  \item \texttt{goal}: \texttt{a1 : B b1 : B a2 : B b2 : B a3 : B b3 : B}
\end{itemize}
\item Specialisation points:
  \begin{itemize}
  \item None.
\end{itemize}
\end{itemize}

C.3.33 ordered

;;; Predicate that checks whether a list is ordered
(define (ordered? xs)
  (if (pair? xs)
      (if (= (car xs) (cadr xs))
       (ordered? (cdr xs))
       #f))
)

Parameter binding times:
- ordered!: xs : S
- goal: xs : S
- Specialisation points: None.

C.3.34 overlap

;;; Predicate for checking whether there is an overlap of two sets
(define (ham-a-or-b? xs) (overlap? xs (cons 'a (cons 'b '()))))
(define (overlap? xs ys)
  (if (pair? xs)
      (if (member? (car xs) ys)
       #t
       (overlap? (cdr xs) ys))
      #f))

Parameter binding times:
- member!: x : B xs : D
- overlap!: xs : B ys : D
- goal: xs : B ys : D
- Specialisation points: Call 1 in member? to member?

C.3.35 permute

;;; Compute all the permutations of a list
(define (permute xs)
  (if (equal? xs '())
    '()
    (select (car xs) '( (cdr xs))))
)

;;; Select x as the first element and cons it onto
;;; permutations of the remaining list represented by
;;; the list of elements before x (reversed) and the
;;; list of elements after x. Finally, recur by moving
;;; on to the next element in postfix
(define (select x reprefix postfix)
